Richard McCollims' post was quite interesting. I don't believe I have seen those references, but I'll look them up. The findings certainly fit with the "dual innervation" model of the ciliary muscle innervation: positive accommodation (increased lens power) is mediated by the parasympathetic

branch of the autonomic nervous system. Negative accommodation (relaxation of accommodation) is mediated by inhibition of the parasympathetic innervation (ie it is not an active process), but there is sympathetic innervation to the ciliary muscle, which probably plays a role in modulating sustained accommodation, and "actively relaxes" the ciliary muscle to reduce the ciliary muscle tone. It is believed to act slowly, far too slowly to help at all in relaxing accommodation under normal circumstances. If you are shocked, hormones are released into your blood stream that can "actively relax" the ciliary muscle. These hormones will also cause a constriction of ocular blood vessels, which may also influence the refraction slightly, and interfere with accommodation. If, under normal circumstances, you are not able to fully inhibit the parasympathetic input to the ciliary muscle, this further inhibitory stimulus may cause "negative accommodation," and cause a hyperopic shift in your refraction. I've played around with the effects of topical beta-blockers on the accommodative response, and suspect that the sympathetic nervous system has probably a bigger effect than people think. However, a "shock" stimulus is unlikely to generate a hyperopic shift of more than 0.25 D, unless the person has a degree of pseudomyopia, or a greater than normal accommodative tone. The "clear flash" phenomenon probably has a different explanation in most people, as most myopes have only slight accommodative tone for distance fixation.

The following suggestion comes from my friend Michael C. Brady, a psychology/music major at Indiana University. --Alex

=====

A possible reason for eye fatigue is that a person may be allocating too much mental attention to visual processes. Or, seeing problems may occur due to too much stress being placed at higher levels in the visual system. It could be that one's brain is demanding more from those poor little eyeballs than the eyeballs can support. (people depend on seeing too much).

It is nicely said by W.A. Mathieu in his book, The Listening Book:

"The eyes are hungry. They eat brain energy."

To alleviate this problem, one must give the other senses of the body the respect that they deserve. Listening, for example, is highly neglected. As you read this, notice all of the sounds in the room that your brain has somehow written off as unimportant. Buzzes, hums, typing noises, maybe a car or something. Maybe another human breathing. Maybe yourself breathing. Now close your eyes and listen. When you open your eyes again, you will feel your consciousness flood with visual noise and your screen of sound grow dim. Work to reduce this effect of visual dominance over your sensory system.

Maybe think about how your little toe on your left foot feels while you read. It may be insightful (or it may be a complete waste of time).

-Oh well, just an idea.
Stay in tune, Mike

Good Morrow to you all!

Ok. I was wondering if any one has heard (or taken) the Silva Method Mind Control? It's is basically a class in meditation/relaxation/etc. Silva has also written some book. Enough for background. I rememeber my teacher telling us a story of this fella who improved his eyesight by meditation and repeating the phrase 'every time I blink my lens adjusts to focus like the lens of a camara' or something along those lines (I took the class in spanish - the original phrase was 'Cada vez que pestaneo mi ojos se ajustan correctamente al foco, como la lente de una camara'). The idea is to repeat the phrase, while meditating a couple times, every day. I *more or less* tried it and I remember notincing some mild improvement (I only tried it for a week or so). Anyways. Any questions/commmnts/concerns welcome!

Cheers & have some sort of a nice day!

the silva method seems to me to be a cross between NLP and TM with some ESP thrown in for good measure. I dont think it can hurt trying it. There is quite a large component of visual problems that are "in the mind". I have a friend who when he takes the drug extasy, can see perfectly, but when he comes back to earth his vision goes sour again. odd. there are well documented cases of

true multiple personalities where one personality is myopic or nearly blind, but other personalities have perfect vision. This to me implies each personality has a "set" of maybe muscular positions which the mind activates depending which personality is awake. Again pointing to an involuntary but modifieable aspect to sight problems.

further along this point Richard Bandler of NLP fame, claims to be able to hypnotise subjects and regress them back to childhood, prior to sight problems, and bring them all back, but leave their eyes back in the pre-problem age. and when they awaken they can see proprely. But he does say this technique doesnt seem to work very well for people with astigmatism.

> "in the mind". I have a friend who when he takes
> the drug extasy, can see perfectly, but when he comes back to earth
> his vision goes sour again. odd. there are well documented cases of

Odd...not really. Since I did get a B.A. in psych. I have heard that

sometime emotional trauma (say witnessing a murder/rape/accident) can cause severe myopia (I read this in a Hypnosis book - a reputable one from a Dr. who name escapes to me....not one of those 'Hypnotize anyone by tomorrow noon' books that we can buy for \$15)..He manage to cure it with myopia. His explanation was that the mind crippled the eye (the mind can 'cripple' bodily functions (for the unbelievers) -as a quick example - people that have 'stress' (say due to a coming exam) sometimes experience sleep/eating problems)...anyways...getting of the subject, he did manage to treat some cases.

Regarding Extasi & your compadre....mmmmm...I dunno if extasi causes alucinations or just turns people hyper....I am not sure if his experience is real.....I am not saying that your friend is lying (no flames please!), I am just impying that his statement or percetions might be unreliable.

Hi,

A week or so ago, someone brought up the subject of NLP (Neuro-Linguistic Programming). I absolutely do not profess to be an expert in NLP, but I have read a lot about it. One of the ideas of NLP is that we often unconsciously respond to messages that we hear all the time. (Any true NLP whizzes out there feel free to correct, flame, or whatever's appropriate if I've gotten this wrong!) For instance, an NLP-er would suggest that we fail to reach our true potential economically because of

all the negative associations we have with money (root of all evil, can't buy happiness, etc). The idea of NLP is to root out all of those negative messages that we've stored away all these years and convert them to positive ones.

Anyway, I decided to sit down and think of all the "messages" I can remember being given as a kid with regard to vision. I realized, in doing this, that I received overwhelmingly negative messages from my overwhelmingly well-meaning mother for years as a child. I remembered her saying, "Sit up straight when you read, OR YOU"LL RUIN YOUR EYES," "Find some better light, OR YOU"LL RUIN YOUR EYES," "Quit reading under the covers with a flashlight OR YOU"LL RUIN YOUR EYES," on and on and on. I actually called two of my sisters to ask them if they remembered this. They did (and thought it was pretty funny, remembering it).

So an NLP-er would say I obediently did just what my mother said I would do; I ruined my eyes (BTW, all eight of my siblings also wear glasses, but my mother, god bless her, never did until old age set in.)

Anyway, now what I do is, when I'm doing any vision training, or just thinking about relaxing to improve my vision, I picture my mother saying, in that same voice: "You'd better cut that out, or YOU"LL FIX YOUR EYES!"

Who knows if this is of any help? It makes me laugh, if nothing else. One other NLP thing I have decided on is to refer to the stuff I do every day as "vision games" rather than "vision exercises." It gives me a different attitude about doing the stuff.

If anyone is more interested in NLP and vision, I remember reading a message by Tad James (one of the NLP founding fathers, I think) in alt.self-improvement. He described using some technique called "Time Line Regression" (I think...) to improve his vision. If you read this newsgroup for a couple of weeks, he's bound to post something else, should you want to contact him.

Alex,

Here is another 'natural vision improvemnt' advocate. The basic premise is to find the point where your vision just becomes blurry and to increase (or decrease) that distance (near/far sighted). To make this easier they use readily available + lenses to get the blur point within arms length. The main benefit of this (for me) is that I have a way to 'measure' my improvemnt that is more objective than, yes, I can see it better. They can be reached at:

Vision Freedom
1665 Red Crow Road
Victor, Montana
59875
1-800-422-7320
1-406-961-5570

You may wish to contact them and see if they are interested in being listed with I_SEE.

I don't know why there is such resistance to natural vision improvement among the 'professionals'. They seem to readily believe that the eye can change to become more myopic but will then adamantly refuse to believe that it can be reversed. If other fields of medicine thought like this nothing could ever be cured only bolstered with ever increasing 'medication/treatment' until it finally succumbed to its 'inevitable death'.

Your prisoners-of-war eye improvement from deprivation of the eye glasses is well documented. Sailors (of yore) tended to have keener vision than average from sighting into the distance long hours. Bates cites many patients that had improved their vision. Many lay people have improved their vision, documented by their eye care (?) specialists. The Vision Freedom folks claim many happy customers, the founder developed it as he needed 20/20 to become an airline pilot, which he did become.

I can understand the eye care profession being hesitant to advocate not wearing 'corrective lenses' from the fear of lawsuits. People get sued for brewing coffee nowadays. I think that before they will even attempt studies there will have to be some major changes in the way lawyers work. Until then we natural vision advocates are on our own.

Hi

A common scenario:

I do exercises, my vision improves.
When I stoped and it got worse again.
What went wrong?

here is a little story. I was talking
to a friend of mine about vision therapy
and he told me this story about his grandfather.
during the great depression my friends grandfather
heard about the bates method. but couldnt find or afford the
book. so he figured being an inteligent man he could figure
it out for himself. here is what he did. he got a card
with some typed letters on it. he held it out till he could
just see it. and each day he tried to move it further out.
over weeks and months his vision improved to the point he didnt
need glasses. and to this day it has stayed that way.

so here is a man armed with no knowledge about vision therapy.
no special tools, no doctors, no books. just a belief and a single
exercise. he got results and kept them.

to answer the original scenario on a different level,
every phenoma can have a plurality of causes. If you address
the symptoms the causes may or may not go away. most likely
they wont. If you address the causes the symptoms will go away.
for some people just doing exercises is not enough there have
to be changes at more then just the immediate physical level. It could
be emotional, It could be structural, it could be spiritual,
it could be as simple as a belief....

I have found each plateau of progress is accompanied with some
sort of other changes. I found my first major change occured
in conjunction with a renewed interest in the arts. Something
I had negelected for over 10 years. I started drawing again,
going to art galleries and generally really getting into the
visual arts.

Currently I am doing a meditation course and learning about
buddhism, something I had an interest in almost 20 years ago, but
got left behind over the years along with good vision.

you can notice improvements straight away. permanent improvements
take a while. Janet Goodrich took 30 months.

the first types of improvements are based on better noticing

what you see. the second is building/enhancing neurological pathways and eventually there will be permanent physiological changes.

the first goal is to start getting clear flashes. ie crystal clear sight which at first may only last a few seconds.

patience and perserverance are the key. once you start getting clear flashes you know its possible. turning VT into daily habbits that what will produce results.

>see them all too clearly in the first place.

sorry. I will try to be more clear. its a perceptual thing.
you dont actually realise what it is you see. your mind just labels
it as blur, without trying to resolve anything in the blur.

as soon as you start paying more attention to your visual input,
you start to see things you have always seen but didnt realise
you were seeing them. classic example is if you had astigamtism
you might be seeing double images, but didnt realise this
until either someone told you or you finally noticed what you see.
double images generally looks like a mess, so the mind just labels
is it as too hard, its a mess. you are making more sense of what
the eyes display to the mind. clearer?

>> the first goal is to start getting clear flashes. ie crystal
>> clear sight which at first may only last a few seconds.

>

>eyes adjusted to the light, for a split second there, I could have
>sworn that I was wearing my contacts. Everything was clear. Is this
>possible after only doing the exercises for one day??

when you have one you know it. there is no doubt. split second
confusion is possibly just a prelude to the real thing.
I didnt have one for about a couple of months, and then it blew
me away. (does this mean the same thing in the states?
have to watch this trans pacific english)

>Also, everyone I tell about this thinks I've totally turned into a

>flake, because they think it's nonsense. Is there any truth to what
>they are saying???

there is plenty of truth to it. refer them to Aldous Huxleys book,
the art of seeing. while never having acheived permanent 20/20 he went from
being virtually blind to being able to read without glasses.
its an interesting story.

most people fail to realise that vision is a dynamic process,
your sight is rarely at the same level of accuity for long.
most people see better in the morning and less well by later afternoon,
whats changed?

Bates equated lying and being lied to as possible myopia-promoting
experiences.

I think honesty may have as little or as much to do with it as any other
personality trait or behavior or experience. I believe myopia (especially
moderate/high myopia) is as little understood as once were all the diseases
that masqueraded under the generic name of "fever" a couple of centuries ago.

"Myopia" is about as precise a term as "insanity" would be precise in modern psychiatry, if it were the only term (and the only approach) they used for 20-odd different conditions.

I do believe that personality traits have a lot to do with it. More than dishonesty (sorry -- can't relate), NON-CONFORMISM strikes me as the single most persistent trait in a (moderate/high?) myope's character. It may not manifest itself in behavior but it does a lot of manifestation in our thinking patterns and the way we perceive the world.

I suspect the outwardly simple problem of myopia in anyone's life really stands for something HUGE. It has a lot to do with WHO we are -- and no simplistic approach can possibly give all the answers. I would imagine extensive studies in cognition and perception aimed at understanding myopia, plus a precise scientific picture of what REALLY takes place in the eye, would solve the mystery. Unfortunately, they've already invented glasses... no incentive to go into it...

Here is another thought. Does myopia correlate with shyness and/or=20 introversion? Being told to "shut up and sit down" during the formative=20 years may lead to an introspective personality. Myopia may be in part=20 due to the attempt to turn the vision inward.

OK, I'm a high myope and a non-conforming thinker,
perceiver, and be-er. A non-conformist is more likely to be
attracted to healing one's vision naturally, thus
eliminating the dependency on the culturally sanctioned
glasses.

(Some non-conformists are angry or confused, however.
Chronic anger would certainly degrade one's ability to
see. Non-conformists are also sometimes excessively
self-focused. Perhaps this, too, narrows the range
of one's emotional/mental/visual acuity.)

Subject: Bicycle ride on an Indian summer's day

Date: Fri, 29 Sep 1995 15:34:34 -0500

Status: RO

X-Status:

Hi everybody,

Today I rode my bike home from work on a bikepath that goes along the lake. It was a good day for looking around because there was a breeze at my back and I didn't have to pedal too much. There was lots to look at, too, from the sun glancing off the lake to the Canada geese on the grass to the downtown skyline off in the distance.

My question is this: has anyone ever had the experience of being in beautiful scenery like this, in which you can see for a long distance, and felt like you were being in some way...fed? I wonder if, with my lifestyle of doing a great deal of close paper and computer work, my residence that is surrounded by trees and three-story buildings that block out the horizon, and my frequent subway travel, I'm somehow starving my eyes or my brain for the long distance looking that our ancestors were used to performing. Maybe there's a lot to be said for just going out somewhere where you can see a long way and feasting on the view.

It seems to have psychological benefits, too. There's something peaceful about being able to take the long view: it makes you feel like there's more stability around you, and it's easier to be at peace.

From: Alex Eulenberg <aeulenbe@indiana.edu>
Subject: Measuring your myopia
Status: RO
X-Status:

Here's a rough-and-ready way you can tell how many diopters of myopia you have. It works for nearsighted people who have little or no astigmatism.

Take a piece of paper with a detailed image on it (a text will do), and find the furthest distance at which the image is absolutely clear. Take the reciprocal of that distance in meters, and you have your amount of myopia. For example, say the furthest distance you can see absolutely clearly is a 0.5 meters, then you have $1 / 0.5 = 2$ diopters of myopia. If you know your prescription, do this test anyway and see how close you come.

>Hey!
>I saw somebody recommending Robert Michael's book (seeing beyond 20/20)
>on a newsgroup!!!! Cool!
>(R-M: thought i'd let you know- people are getting the word out :-)

Thanks for the feedback Marco. Actually, Seeing Beyond 20/20 is no longer in print. The new edition is called Seeing Without Glasses and is available from Beyond Words Publishing in Oregon. Phone 1-800-284-9673 to order.

Here is a recent article I wrote for parents: Enjoy, Robert-Michael Kaplan.
Helping your Child's Vision...naturally!
By Robert-Michael Kaplan O.D., M.Ed., FCOVD

"Mommy I can't see the television clearly." "My eyes hurt when I read."
Many parents hear these complaints from their children or observe their child's squinting and straining when playing computer games or reading. As a conscientious parent you take your child to the optometrist or ophthalmologist and you hear the dreaded news from the eye doctor "Your child needs glasses or a surgery." You then do what your parents probably did and believe the doctor's opinion as being the only choice you have, and you get glasses for your child or surrender to a medication or surgical procedure.

If you are prompted to seek out second opinion you might even be interested in hearing about a complementary approach you can use to help your child's vision. As a parent myself, I have been concerned about my 4 1/2 year old's son eyesight, especially because his mother has a history of nearsightedness and astigmatism. Many years ago while researching vision as a Clinical Professor of Optometry, I uncovered some amazing facts about the possibilities of recovery for eyes and vision. I want to share these with you so you and your family might benefit as my wife and son have. My wife has reduced her dependency upon glasses by 90% and when she does wear eyeglasses, they are 90% weaker in strength. My son is maintaining his sharp eyesight and is developing good visual habits.

Like your body's muscles which can increase function, so your child's eye muscles can be trained to work efficiently and effortlessly as well as increase their fitness. The increased vision function and fitness results in sharper eyesight without the dependency upon addictive and strong eyeglasses. Just as you would introduce physical therapy to restore function to an ankle injury, so the eye muscles respond to vision retraining. Even for those children who are already wearing glasses, vision fitness can be enhanced. Imagine the excitement of going back to your eye doctor and getting weaker lenses. This is happening for many people.

Here is what a family have seen:

"I was very disappointed when my doctor told me that David would need glasses and surgery in order to correct his wandering and lazy left eye. I just couldn't imagine this young boy's eye being cut into. I decided to find another approach to dealing with his problem. A friend told me about this doctor who had cured his own vision problem without surgery, drugs or glasses. It took a while to find him, but our first visit convinced me that

I was going to use Dr. Robert-Michael Kaplan's complementary approach. He explained everything in great detail and began teaching David and I how to improve vision using very simple exercises. He sent us to a colleague who weakened David's prescription lenses according to specific directions he gave me. I was told that these glasses were a special vision fitness type and David would only be wearing them for a short period. The weaker prescription allowed my son to focus, but at the same time, he had to retrain his brain to teach his eye to see more clearly with the weaker lens before left eye. I was amazed how quickly the results happened. After just four weeks of combining patching of his better eye and wearing the vision fitness lenses, George could see five lines better on the special eye chart we were trained to use. Nine months later, he was out of glasses 90% of the time and this past spring he had no trouble seeing the blackboard. Now our training program is oriented towards getting his two eyes to work better together. It is very obvious that no surgery is going to be necessary to alleviate David's eye problems. I have also noticed an improvement in David's ability to learn at school. It seems that the way he uses his eyes has brought about better school performance. What a wonderful side benefit I didn't even expect."

HEALING EYES AND VISION
by
Robert-Michael Kaplan, O.D., M.Ed. FCOVD.

Healing is an ongoing process. It is taking place inside of us, and around us, every moment of the day. The regeneration of the vital essence of who we are occurs when our inner being is aligned and connected to the greater universe. Very little is needed for this healing process to maintain its vibrancy. As long as we stay conscious and present to this natural process, our bodies stay well. When busy-ness of our modern day living disconnects us from our essence healing is compromised.

The original role of doctors was to co-facilitate the re-arrangement of the conditions in such a way that the balanced relationship of mind, body and spirit encouraged healing to occur on its own. Somewhere along the way, communication between doctor and patient became confused and doctors began taking the credit for the healing process rather than acknowledging the patients' full responsibility in this process. The marketers of drugs, medicines, vitamins, minerals, and herbs told us that substances outside ourselves were the true healing agents. Doctors provide the external stimulation to revitalize the natural healing phenomena within each of us. Usually, healing occurs free of symptomology. The presence of symptoms like body aches, pain in the eyes, and malfunction of organs, is an indication that an upset exists between our inner consciousness and our resonance with life. The presence of symptoms is a reminder for us to either initiate or reconnect with our essence, our light, our spirit, or

to use some external aids to facilitate or aid the healing process.

Allopathic Way of Looking at the Eyes

Like the body, the healing path of the eyes and vision has been viewed in the same way. Most modern-day consumers of vision care have been led to believe that an optometrist or ophthalmologist can improve their eyes. The western form of vision care has evolved primarily into three methods:

- (1) wearing glasses or contact lenses,
- (2) using eye medications, and,
- (3) having surgeries performed on the dysfunctional structure of the eye.

The belief in these three options is so ingrained that well-known research and clinical documentation about other healing modalities for the eyes and vision have been buried in dark libraries and filing cabinets around the world. Just as other parts of our body respond various forms of self-healing, the eyes and the process of vision have a built-in healing mechanism that responds to an appropriate balance of outer stimulation such as nutrients, light, lenses, colour and self-governed inner participation. The appropriate combination lock or recipe provides the homeopathic impetus for self-healing. Some of the input for this holistic approach comes from practitioners, books, and self-experimentation from as far back as three thousand years.

The Eye Sees What the Mind Projects

If we believe that the tools and methods utilized by various practitioners actually cause the healing, we become entrapped in the allopathic model. We must move beyond - and see beyond the old way that states that any condition in the eye is a problem. Rather, the eye condition, whether it be nearsightedness, astigmatism, old-age sight, glaucoma, cataracts, or macular degeneration, is the computer printout or facsimile of what is needed (a combination of the outside and the inside) to begin the homeopathic self-healing process. For some, this thinking might seem quite radical, given the embedded status quo position of eyeglasses, contact lenses, eye medications and surgery. Complementary methods facilitate the healing of eyes and vision by first encouraging a shift in the patient's attitude or belief system. Once self-limiting beliefs have been released, and the necessary outside aid for the eye prescribed, the process of natural healing of the eyes and vision may begin.

From a healing perspective, your eyes are designed primarily for two reasons, the most obvious being their capacity to receive light. Like a satellite dish, the retina of your eye is curved to permit light from the sun to be captured and focused through the cornea, pupil, lens, and vitreous humor onto a single point on the eye's structure and the surrounding retina. The fovea (a pin point depression in the retina) can be considered the point of intellectual rationality, while the retina stimulates feelings and emotions. Seventy-five percent of this light is transmitted through electrical neurological transmissions to the part of the brain associated with eyesight, logic, and clear vision. The remaining twenty-five percent is converted into energy that travels to the hypothalamus, the master conductor of the body, which takes the colourful ingredients of white light and directs it down through the autonomic nervous system to all the sub-systems such as the endocrine, pituitary, adrenals, and other glands which regulate the body's hormonal and emotional functions.

The second aspect of the eye is its natural capacity to project light. The unconscious mind, through the brain, has the ability to project a thought, an attitude, a feeling, or an experience and permit it to block the eye's

capacity to receive light. Coupled with the influence of the mind, our eye's perceptions can be affected by the state of our emotions, . It is as if our thinking, our state of consciousness, can impact the eye in such a way that an allergic reaction is set up to influence the retina's natural way of dealing with incoming light. Therefore, the area of the brain that regulates eyesight, the visual cortex, as well as the hypothalamus, can be missing some of the vital nutrients provided by the incoming light through the eyes. When this situation persists, the autonomic nervous system has to draw from its own reserves to restore homeostatic balance initiating what Hans Selye called "distress." Permitted to continue over time, dis-ease, and later, disease set in. The eye records the brain's response to distress in the form of symptoms such as blurry vision, headaches, double vision, and pain. As these symptoms continue, the structure of the eye begins to permanently imprint the altered behaviour. Optometrists and ophthalmologists will measure this distress in the myriad of diagnostic terms that have been coined to classify abnormal eye conditions.

What The Eye Conditions Mean

During the past twenty years, I have been documenting patients' symptomology, their measured eye prescriptions, their case histories, and the parts or structures of the eyes correlated to their individual life experiences. Each structure of the eye has its own part to play in maintaining healing and well-being.

Healing the eye and vision is a matter of identifying the primary symptom of the distressed part (section) within the eye and stimulating the person's own capacity for self-healing. Once the emotional metaphoric equivalent of the eye condition (See Eye Condition Table) has been described in relationship to the person, the doctor can provide the outside support for the patient to initiate his/her own healing.

The eye condition, either described by the patient, or diagnosed by the doctor, is an subconscious message calling out for a specific assistance. The S.O.S. call reveals a visual metabolic and emotional system out of balance. The outside homeopathic approach includes sound nutritional principles, specified amounts of light and colour, and programmed self-healing visualization and imagery. The patient now possesses the tools to help himself.

There is a relationship between the eye structure, the patients' behaviour, and food and nutritional herbal supplementation available to assist them in the process of healing of their own eyes and vision.

The western allopathic model of dividing the eye into components and treating individual parts separately from the whole does not support the holistic model of healing. Rather, consider an analysis of the eye parts and a subsequent reintegration into a whole-person healing focus that takes all aspects of human behaviour and consciousness into consideration.

Beyond 20/20 Vision=81

In the early seventies, as I began to heal my own eyes and vision, I integrated the methods I was using into the dynamic, holistic vision approach of "Seeing Without Glasses", incorporating many healing modalities including modified lens prescriptions. The new lens prescriptions are usually weaker in power and act as a biofeedback device. The clarity achieved through these lenses, coupled with lesser percentage of blurry vision, provides the ideal recipe for modifying visual awareness. When you are eating foods that do not agree with their system or is experiencing emotional challenges, the eye blurriness can increase. On the other hand, when you are clear at all levels of your being and can receive light

and project back accordingly, blurred vision is minimized. With appropriate vision training techniques, that small degree of blurriness can be permanently reduced. Eye patching is also utilized and the patient is asked to look through one eye from which a homeopathic effect is generated within the eye structure and passed through the visual pathway. Thereafter, your lens prescription can be further modified, usually lessening the layers of artificial lenses. Over time, a lower dependency and need for glasses and an accompanying improvement in eyesight in your naked vision state can be observed.

This holistic approach also includes the use of wholesome foods, nutritional and herbal supplementation, which both build and therapeutically heal the eye structures and vision function. Processes are designed to open the patient's blind spots and deal with visual and other denials.

The influence of the family tree and the transgenerational implications can be further understood by a process known as Rayid Iris Interpretation. The way a person sees and deals with life can be controlled by these hereditary influences. Specific therapeutic applications from this interpretation process help breakdown the subtle controls from the genetic makeup. Last, the use of varying kinds of eye patching serves as a way to retrain processing through the left and right eyes. The evidence to date strongly suggests that the right eye perception as well as the patterns on the iris correspond to the fathers' side of the family tree. Likewise, the left eye relates to the mothers' side of the family. Therefore, any training necessitates equal viewing through each channel prior to initiating an integrated binocular two-eyed state.

The following case studies illustrate the healing possibilities that can occur in the eyes and in the process of vision.

Case Study One - Sue

Patient Sue, a vibrant 37-year old professional woman, came to my office with symptoms of blurry vision and occasional periods of blindness in the right eye. She had been previously diagnosed as having multiple sclerosis and had spent short periods in hospital for immobility. Sue's very stressful job sometimes required sixteen hours a day. After hours, she did not have much time for herself or the pursuit of her interests, recreationally or personally. When I checked on Sue's ability to use both eyes together, I noted that she saw primarily through the left eye. Her field of vision and ability to perceive through the right eye at the time of her first visit would have classified her as legally blind.

Studying the iris pattern and comparing the right eye and left eye, it became apparent that some controlling influences were present from the paternal side of the family i.e., the "jewel" (mental controlling rational markings) was present predominantly on the right eye. Sue revealed her deeply imbedded fears about relationships with men, particularly her father. Sue, who had already begun modifying her eating patterns and practising de-stressing techniques, communicated her misgivings about her previous multiple sclerosis diagnosis. She had never felt comfortable with this doomsday assessment and began to take self-responsibility for her well-being.

During our two-hour session, I initiated an eye mobility and body movement program performed to music. I patched her left eye, which proved very effective as a healing stimulation and coached her on specific releasing statements around her relationship with her father. I also suggested specific vitamins and minerals such as high potency B-complex, vitamin A, zinc, selenium, vitamin E and C, in order to provide the nutrients needed

for rejuvenation of particular eye structures associated with central and peripheral vision.

After four months, on her second visit, Sue showed remarkable improvement. Not only was she able to use her eyes together for short periods of time, she had also begun a movement exercise program as well as modifying her fast-paced professional life by taking on less responsibilities and participating in more self-growth experiences. Remarkable behavioural changes included self-confidence and capacity to listen and be still versus her earlier need to talk constantly. Sue seemed like a new person. I could see light coming from both her eyes, rather than from just the left, she no longer overcompensated by being overanalytical or justifying every action or statement she made. Those visits were recorded on video tape, improvements in her eyes and vision were quite obvious. While her healing continues, Sue has entered into a primary relationship with a man and is reevaluating her career path..

Case Study Two - John

John, a 65 -year old former banker, suddenly developed blindness in a specific quadrant of his left eye. The structure on the iris relating to the position of loss of visual field corresponded in his iris to the heart area and was associated with commitment and ability to express love. His case history revealed a man now free from the daily pressures of work and who, in retirement, was now facing years and years of past denials in his home life and particularly his relationship with his wife. The loss of visual field in his left eye corresponded to his female perceptions. The female person closest to him was his wife, and metaphorically, he was blocking her out of his sight. His distressed vision, like a computer printout or fax from within, revealed a new opportunity to deal with these formerly shut-off feelings.

As facilitator, I provided John with the tools and aids for his own self-healing, suggesting he begin a program of patching his right eye and using a specially designed lens in front of his left. The intense focus of light through the left eye over and above the right and the focus through the therapeutic lens, set in place a form of visual homeopathy that forced John to pay attention to his feelings, his actions, and his behaviour. He continued the program on his own using only his left eye for a maximum of four hours per day. John embarked upon a healthy eating program, practised relaxing techniques, and dealt with the denials in the primary relationship in his life. John was also able to set up a change in visual field through a monitoring of the lowered pressure in the eye.

On his return visits, John brought me many drawings of his perceptions of the blind spots through his left eye, which were now smaller. Each day, John listened to a self-healing audio tape that I made for him where he imagined himself being very small, travelling inside his eye with a little black doctor's bag, full of the ingredients and natural resources to feed particular parts of his eye and injecting it with healing nutrients and spraying it with different coloured lights.

Case Study Three - Joan

At her first visit, 31- year old Joan, a health care provider, was wearing contact lenses for nearsightedness and astigmatism, for most of her waking hours. Her goal was to find ways to free herself from the dependency of contact lenses and glasses. A highly intelligent woman, Joan seemed very committed to begin an eye training program that was to span nine months, also participating in my group glasses. Using the techniques of patching, coloured light, vitamin and mineral supplementation and healthy eating practices, imagery, and self-healing, I was able to provide guidance for

great behavioural optometrist. Tell him I referred you, and he will take good care of you.

My new book is now out. Hooray! 3 solid years in writing. For those of you interested, here is some more information:

New Release

The Power Behind Your Eyes

Improving Your Eyesight with Integrated Vision Therapy

By

Robert-Michael Kaplan

Price \$16.95 U.S. Paperback: 180 pages 26 Black and white illustrations: 8" X 10"

ISBN 0 89281 536 1. Available from Inner Traditions, 1 (800) 488-2665 - and most book stores.

Vision occurs behind the eyes. That is where the real power comes from. The Power Behind Your Eyes takes the stand that 90% of vision emanates from the mind, and that by implication each individual is ultimately responsible for the way they see.

The Power Behind Your Eyes looks at the causes of eye problems from a metaphoric point of view. The reader is guided through very practical activities that invites them to examine their life as part of the way they are seeing. This book is an example of the new paradigm of vision care.

"The Power Behind Your Eyes, starts where my first book Seeing Without Glasses ends, that is vision fitness. I decided to write this book because my patients kept telling me these incredible stories about how their lives were changing as their vision improved."

-Robert-Michael

Kaplan. Oct., 1995

"The Power Behind Your Eyes is an important book that can help you create a new vision for your life".

-Deepak Chopra, M.D. author of Seven Spiritual Laws

of Success;

Ageless Body, Timeless Mind;

and Quantum Healing.

Good vision is more than the ability to see 20/20 on an eye chart. It is product of a healthy way of "seeing" one's self and the world. Any vision problem is a message alerting us to an imbalanced inner state. Eyeglasses, medications, and surgery may treat the symptoms of poor vision but they cannot correct this inner imbalance. The Power Behind Your Eyes presents a new system of eye care - a comprehensive daily program that can actually improve poor vision.

Drawing on over two decades of clinical research, the author combines powerful new treatments-light and colour therapy, creative visualisation, palming, acupressure, nutrition, and the prescription of weaker lenses - with standard methods of diagnosis and treatment. Dr. Kaplan trained in optometry, education, psychology and the Tibetan healing tradition, unites Eastern and Western medical philosophies in his practise of Integrated Vision Therapy. More comprehensive than other vision care techniques, this therapy takes a true holistic approach to identifying the causes of vision problems and developing noninvasive, natural strategies for treatment.

With *The Power Behind Your Eyes*, you can claim responsibility for improving your vision through a series of clear, easy-to-follow exercises, diets, and changes in daily habits. Included in the book are most of the charts and visual aids needed to reclaim your eyes' natural power.

Hello and festive greetings:

A patient of mine recently wrote the following after visiting my retreat center and completing a vision therapy session. I trust it will inspire you as it did me. I wish you all happy new year and clear vision.

"My directive is to see clearly. I drive down a quiet road in the country. Looking through a lens prescription twice reduced, I negotiate toward the parking lot near the ocean. It is a windy and rainy winter day. No one is in sight. Closing my car door, I remove my weaker glasses placing them in my pocket. I reach for my strongest glasses. They represent years of suppressed perceptions. I have witnessed much through these lenses that no longer satisfy my improved vision through my eyes. I know it is time to let them go. I negotiate my way down the walkway to the rocky outcrop near the water. I walk carefully looking for flat rocks to climb on. Once at the edge, the wind is much stronger and gusts send sprays of water flying over my face like a cold shower. I know why I am doing this. The ocean gods are to help me release the addictive hold of my past vision. The strong glasses in my hand represent these limiting perceptions. I glance at the changing patterns of the waves. As I think about the ocean goddess, my right hand goes up in the air and I toss my glasses for her safe-keeping. As they leave my hand, I lose sight of them in the blur. My past vision is now buried in the ocean, and I can see free of my illusionary past. I walk back

to my car feeling liberated."

>
>May I be so bold as to request a jargon-free paraphrase (hopefully
>cross-posted to I_SEE)?

Please note: This is not OEP (which means Optometric Extension Program)
A jargon free explanation. Wow, another challenge! Strong glasses cause a
stress breakdown of the two eyes working together. I believe that this
causes the addictive relationship with minus lenses.

>
>And what about that 25% of myopes without that fixation disparity
>problem? What happens to them when you give them a 20/40 prescription?

This is a good question. First, I make sure that the reduced lenses doesn't
now cause a fixation disparity, and if not, I suggest the lens for 20/40,
and if it does induce a breakdown of two-eyed vision, then I give the lens
which causes the least binocular disturbance, and include integrated vision
therapy.

>
>And what do you do when you get a 1.00D myope who's never worn glasses?
>Do they have the same kinds of fixation disparity rates?

Yes, a little minus can go a long way in inducing a two-eyed disturbance

>
>And, while I'm here, I've got another question: can you explain your
>theory behind overcorrecting astigmatism? This strikes me as very weird,
>since all my favorite authors (Kennebeck, Raphaelson, Prentice, Simpkins)
>are adamantly opposed to cylinders.

This is a very difficult question to answer in a short form. I'll give a

try, otherwise when we work together, I 'll teach you the mechanics. By definition, astigmatism means one area of space is more blurry than another. The separation is usually by 90 degrees. In the simplest example, the vertical meridian of the cornea would show more myopia than its horizontal counterpoint. Here is the essence. The person's learning is to begin to see through the vertical meridian. This is the area of space that is the most blurry, and represents the most blurriness in their life. In later discussions, I 'll demonstrate that the vertical meridian has particular psycho-emotional correlates. If my hypothesis is correct, then the lens the person looks through, should accentuate light focusing more on the vertical meridian than the horizontal. The only way this can be accomplished is to increase the astigmatism for myopia, although we can reduce the astigmatism in farsightedness. If you just leave out the cylinder, then the person learns to see more clearly through the horizontal in this example. Granted their eyesight may improve, however, their discovery of the learning they need to get to the cause of the problem is never addressed. This is the distinction between integrated vision therapy and say regular vision therapy or even vision improvement. Phew, that does it for now. All the best, Robert-Michael.

Regarding the letter chart sent by Vic:

Some letters are more visible than others; letter charts should contain only letters of approximately equal visibility. An example of an excellent letter chart is a Bailey-Lovie LogMAR chart, available from the National Vision Research Institute (NVRI) in Melbourne, Australia.

The only 10 letters used on this chart are D E F H N P R U V Z.

They were chosen as they have similar visibility at the same detail size. The Smith-Kettlewell Institute use the same letters, I believe, for their SKILL card, etc.

If you do not use similar visibility letters, your measures of acuity will change according to the combination of letters you place on each line.

thanx for that info. here is a new and improved version
to generate new charts just change the number 758 to
anything you like.

the first letter of the random chart is always the same
to give you a starting point.

X-Status:

hi all.

here is a section from the latest version of the FAQ.

Since I have been getting amazing results,
I think it is worthwhile posting this here first,
so people can play with it before the new release
of the FAQ

Almost everyone has some degree of astigmatism, as no eye
is perfectly round. So if you have any noticeable astigmatism
which the following will highlight then you can use it to
your advantage to gain overall clearer sight.

all comments appreciated.

have fun

Vic

[9.21] What is the astigmatic mirror?

It is an indispensable tool for eliminating astigmatism.

Send the following program to a postscript printer.

```
-----%<-----cut here -----  
/ZZ { 0 30 moveto 0 250 rlineto 4 setlinewidth stroke } def  
gsave 300 400 translate 40 -1 0 { ZZ 10 rotate } for showpage  
grestore  
-----%<-----cut here -----
```

If you don't have access to a postscript printer, then follow these instructions, else skip over the next paragraph.

You will need an A4 sheet of paper, a ruler, a protractor, a compass, a pencil and a 0.2mm black marker. Find the center of the paper, and using a pencil and compass draw a circle almost as large as the paper (diameter 20cm) with the center of the circle at the center of the paper. Draw another smaller circle from the same central point about radius 1cm. Then draw a line cutting the large circle in two, but not crossing over the inner small circle. ie Leave the inner small circle blank. Then divide the two pie wedges you have in two again. Again not drawing inside the inner circle. Now you have 4 pie shapes. Then divide each of these in two again, so you have eight wedges, and then again so you have 16 and then more one final time. So you have a spoke about every 10 degrees. The result looks like a bicycle wheel. Now using your marker draw over the spokes of the wheel with nice sharp dark black lines, make sure all the lines are the same darkness.

Now you have your black on white wheel. Use a bright yellow and bright orange fluoro highlighter. The colours aren't important and you can even just leave it black and white. Outline each spoke of the wheel with the orange highlighter and fill in the gaps between spokes with yellow. Leave the inner circle white. Later you can experiment and choose colours that please you. The bright colours are useful because they attract the mind, and stimulate all the visual meridians.

So now you have a picture of what looks like the iris of the eye. Place it on a window at eye height, and get back far enough so you can still make out most of the lines with your glasses/contacts off.

Okay Look at the lines near the center. What do you notice? If you are astigmatic you will notice that some of the lines are darker in some directions than others. Get used to the wheel for a little while and experiment with it. Try tilting your head or looking at it sideways. Try looking around the inner or outer circle. Try just staring blankly past the wheel. Notice what happens in each case. Try blinking or yawning. Try palming for a minute or two. Try covering each eye with a hand quickly to see what the difference is between your eyes.

If you are a "typical" astigmatic, you may find the lines near the horizontal are clearer and darker than the lines vertically. You may also find the lines near the horizontal are spaced further apart and the vertical spaced closer together. You might also

find the inner circle in not quite round.

Try looking at it with your glasses on. If your glasses fully correct astigmatism, then *all* the lines should be the same darkness and distance apart. If your glasses do not correct the astigmatism properly than you will still see some lines darker than others.

[9.22] How do I use the astigmatic mirror to reduce astigmatism?

The astigmatic mirror gives you a direct and accurate record of your condition. You can use it as a direct feedback device, a mirror in which any changes you can make and learn to make will be instantly displayed.

Say you find the lines that are horizontal to be darker. Your aim is to make the vertical lines darker. So begin by removing any glasses/contacts, relaxing and taking a few deep breaths. Blinking naturally and breathing normaly, find the line which is the faintest, and move your eye slowly and deliberately up and down that line, imagining it to be getting darker and darker. Tell your self to relax, relax. And imagine that line to be getting darker and darker. The key is to relax your eye has much as you can. You may want to start by massaging around the eye, and maybe doing a couple of minutes of palming.

With a bit of practice you will be able to make the lines in any orientation darker than the rest, but your goal is to make them all equally dark.

If you are myopic its worthwhile to place your wheel on a window, as you get a lot of contrast between the black and fluoro colours of your wheel, and also you can check out the window to see what effect playing with the wheel is having on your vision.

Its also very worthwhile putting one up at work and at home and whenever you get a break you can play with it and see what happens.

The astigmatic mirror allows you to leverage your own visual distortion to work for your benefit.

From owner-i_see@indiana.edu Mon May 22 20:27:51 EST 1995
Date: Mon, 22 May 1995 20:17:38 -0500 (EST)
From: Alex Eulenberg <aeulenze@indiana.edu>
Subject: Make your own eye chart!
Status: RO
X-Status:

For those enterprising souls out there who would like to laserprint or draw by hand their own eye chart, here are the specs:

Distance (feet)	70	60	50	40	30	20	15	10	7	4
letter ht (mm)	31	27	22	18	13	9	7	4	3	2
letter ht (pt)	88	76	63	50	38	25	19	13	9	5
font size (pt)	152	130	108	87	65	43	33	21	15	9

"Distance" is the distance a "normal" eye is able to read the letter. So

if, at 20 feet, you can read the letter of height 22 mm, this means you have 20/50 vision.

The font must be Courier (or Courier Bold) in order for the "font size" in points to correspond to the indicated letter height.

The I_SEE home page now contains an RTF version of this chart, which only works on Macintosh computers, I am told. There is interest in a postscript chart (and I'm sure a Windows compatible chart as well). Any volunteers?

--Alex

You can get one FREE from

The American Association of Ophthalmology
1100 17th St., Washington, D.C. 20036

Or you can download one from the I_SEE home page, Macintosh RTF or PostScript.

http://silver.ucs.indiana.edu/~aeulenbe/i_see.html

Also, an eye chart or two usually comes with most of the vision improvement books listed in the bibliography at the above site. /Better Eyesight Without Glasses/ comes with a nice big fold-out chart.

Another great book with several eye charts (and lots of exercises) is /Total Health at the Computer/ put out by the Cambridge (Massachusetts) Institute for Better Vision. They incidentally sell a wide range of vision improvement tools. Their phone number is (508) 887-3883.

I SEE member Robert-Michael Kaplan, author of /Seeing Without Glasses/ (which also contains some eye charts), runs a company called "Beyond 20/20 Vision" which also has a catalog. Email: <Beyond_20/20@Sunshine.net>.

Leslie, I've used pinhole glasses, and also had a hard time finding them. I finally found them in two places: cheaper ones with bigger holes at a local health food store, and expensive ones with smaller holes from a catalogue (1-800-634-9057). I decided to stick with the larger holes because they let in more light and can be used in darker situations, such as indoors. The smaller holes focused my vision more dramatically, but I could really only use them in brightly lit situations. They really help you focus, and I find that they make my eyes feel really good and relaxed, but my partner says they give him a headache, so I guess you'll have to see for yourself. Good luck.

Subject: Pinhole Glasses update

Status: RO
X-Status:

I just called the supplier of pinhole glasses mentioned in the previous post (Pacific Spirit 1-800-634-9057). The saleswoman, "Shannon", said they were discontinued because "the state" wouldn't let the maker sell the glasses with a full moneyback guarantee. Of course, the manufacturer wouldn't be able to sell them at all without the guarantee, seeing that they shouldn't work according to any mainstream theory of vision.

Sounds like good evidence that pinhole glasses do work, despite current theories, and some opto-organization put some pressure on some legislators to stop them from being distributed.

By the way, you can make your own pinhole glasses by looking through a comb.

<I wondered if any one has any experience with <pinhole glasses. Have they used them, how effective <did they seem, where can I purchase some, are there <different kinds?

Larry:
I have written a paper on improving vision with pinholes, and have been using them myself for years. For someone wearing a strong refractive lens prescription, the pinholes affords one the opportunity to rest the eyes and mind while still maintaining a relative high level of visual acuity. I use them to train my near vision and perception. I find if I practise zooming my focus near and far and then trace a path around the little holes, when I take them off my near vision is significantly clearer. In this way I avoid the trap of becoming addicted to plus lenses for reading. My natural vision fitness stays very sharp, unless I eat foods that I am allergic to (not aspartame), or I lack sleep or become overly stressed.
The pinholes, like the headpiece you described, can be a good way for you to check your visual posture. I describe a similar technique I learnt from a Bates teacher, I call fencing, in my book Seeing Without Glasses, where you can observe the height of the two wires while looking past them. I find the little holes in the pinholes do the same thing for me. Any more thoughts, let me know.

this has not been a very helpful post, I am afraid.

pinholes are useful! if you need to see for extended periods of time
then pin holes will allow you to do so without straining.

If you are like me and your eyes hurt after using a computer all day, then
pinhole are a viable alternative.

pinholes may help any tension problems you do have, by teaching your brain
to relax and not squeeze your eyes.

my behavioral optometrist highly recommends them.

Vic

Pinhole glasses, however, consist of many many holes. A perforated opaque lens, if you will. It is not the same thing as the "lens" of a pinhole camera. The result of looking through it with an improperly focused eye is not one clear image, but a kaleidoscope. (Why this is, I don't know. You can get the same effect by looking through a comb.) Learning to focus correctly reduces the multiple images.

Some myopia researchers have proposed that myopia is caused by the eye elongating "in response to blur" although the mechanism for this is unclear. Many people have noted, however, that people tend to focus for near (optically equivalent to elongating) as a reflex whenever they see anything blurry, even a distant blur. If this is true, by eliminating blur, and replacing it with a kaleidoscope, it might encourage more appropriate focusing behavior. That's just my guess. I've never heard anybody else explain it this way.

Well, I suppose there may be more than one product that is sold as "pinhole glasses" but the ones I have seen have many pinholes (at least 50) in front of each eye. This would remove the problem of "trying to line up a little hole with what you're trying to see".

Maybe the original poster would let us know if in fact the glasses he/she was talking about have only one pinhole in front of each eye.

Sorry, Alex, but it IS the same as the pinhole camera. You can get a fine
photo using a shoebox with one pinhole or multiple pinholes. Not a
kaleidoscopic image at all. It's simple geometry.

And the comb is analogous, using multiple steopaic slits. Same thing.
When I look thru a comb, uncorrected, at a tree, I see one tree. No
kaleidoscopic multiplicity.

When you look thru your pinhole glasses, you see one tree also.

I don't think so. I think a lens which places the object at your far point
is more effective in eliminating accommodative effort.

Bill

>the need to wear glasses?

It's just an optical trick. Increases your depth of focus by stopping down (just like a camera f-stop) the system and eliminating the out of focus rays. Using the same principle you can make a camera out of a shoe box and a pinhole at one end. Both are interesting quirks, neither are very useful in real life.

I asked this because the brochure that comes with
>my pinholes says that they promote blood circulation and exercise the eyes.

That claim is fairly preposterous on its face.

>My eyes certainly feel tired and "exercised" after a while. Yet none of this
>is mentioned in the posts so far.

Haven't seen the others; just joined this list. You may be getting some asthenopia from straining to see. They reduce the incoming light by over 95% so you're operating in a pretty dim, though clearer, environment. Plus you have to keep trying to line up a little hole with what you're trying to see. Probably hard on your neck muscles, too.

>
> The instructions also warned against use of pinholes in dark conditions.

>How dark is too dark?

Less than 5% of dark is REALLY dark.

Is it okay to watch TV at night with ordinary room
>lighting? I certainly hope I am not damaging my eyes by doing so, as I

use
>my T-glasses most often during TV,

No harm done, except to your ego when anyone who sees you doing this starts laughing.

>
> There is a significance in degree between my eyes. The FAQ said to use
>patching, but I find it cumbersome and uncomfortable.

Patching won't help unless you've got amblyopia (lazy eye), a condition which only occurs when one is turned (crossed, e.g.) or when the refractive errors are much different (anisometropia).

Do pinholes help? One
>might think so since the images received by both eyes are now equally clear,
>the brain won't favour one eye over the other.

Not in the case of amblyopia. The brain would still favor the non-amblyopic eye.

>

> Please answer this seriously as I feel that the pinholes is one of the

X-Status:

To be more 'serious', I would say that there might be a protective feature in the pinhole glasses, especially when viewing a nearby electromagnetic emitter such as a computer screen. This could be easily studied.

Also, I believe that pinholes may actually *increase* accommodative effort, another thing that could be easily studied and measured. The human vision system accommodates to blur and certainly the image thru pinholes is blurred, although of course less blurred than without, in the case of ametropia.

Bill

I've never been a much of a photographer (the Kodac "point and shoot" cameras work best for me!) and Geometry is not one of my favorite subjects. My uncorrected vision is around -6.0 in each eye. I get the "kaleidoscope" effect that Alex mentioned when I use my pinhole glasses without corrective lenses. Even with this effect I have about the same amount of correction as with my 20/80 reading/computer glasses. Of course, they work much better outside on a sunny day. They are not as effective inside or with dim lighting.

John

Hi,

Just a few corrections.

>
> >Here's my question:
> >
> >My soft extended-wear contact lenses start wearing out about 9 months
>
> extended wear lenses are not very good for the eyes, and you should
> have frequent check ups. common problems include veins growing
> accross the retina, due to oxygen deprivation. build ups, infections etc.

Veins don't grow as a result of lens wear. The only place that there
is any change is in the cornea, and typically there is an
inducement to capillary formation (neovascularisation) from
induced hypoxia.

Other major complications include;
- increased threshold corneal thickness
- changes in the corneal endothelium
- greater risk of corneal ulcer(s)

>
> as far as vision is concerned, contacts dont correct astigmatism
> very well, cause they tend to rotate around on some people. so
> you may find glasses give clearer vision. its not really know
> just what this poor correction of astigmatism does.

soft contact lenses may not fully correct the astigmatism if
there is rotation. RGP lenses do a better job provided that the
astigmatism is corneal and not lenticular.

>
> If you want to improve you should give yourself as many "lens-free"
> days as you can manage. You may even be better off getting normal
> daily lenses and wearing them only while at work and using glasses
> for things like driving.

If the script is very high then contact lenses give better image
formation owing to the back vertex power of the lens being closer
to the nodal point of the eye.

>
> >My eyes don't really get irritated, except in summer when I am subjected
> >to blasts of dry air-conditioned air and my eyes get stuck in the open
> >position with the lenses cemented firmly to them, or in conditions where
> >even normal-sighted people would have problems.

air conditioning affects contact lenses due to the low humidity of
air conditioners causing higher surface evaporation on the lens.

Hello Glenn,

Sorry about the delay, I have been on vacation.

I am glad to see some interest in PCM. I have posted to some news groups but have not gotten any responses. I seem to be a lone duck here with any PCM experience. Since I am a patient, and I only see the doctor once a month, my answers will be slow if they are too specific.

I started Jan 15, 1995 with -5.0 and -4.75. My last exam was -1.25 and -1.75. Some mornings when I wake up and take off my molds, I can see the leaves in the trees and notice the sun splarking off a spider web (which is just outside my bedroom window) from across the room. I was excited the first time I noticed this difference. :-)

My astigmatism was gone the first week. Peripheral vision is unaffected as far as I can tell. I believe there is a success rate of 97% (3% is the drop out rate). It is not a fast eye sight correction method, but I think it is faster than the Bates method (which might have an even higher drop out rate). It is also not cheap. The program starts at \$1900 with each mold at \$80. The prices could be higher or lower depending on where you are located and the degree of correction needed.

The following is from a pamphlet I got at the doctor's office:

Page 1
Precise Corneal Molding(tm) - PCM(tm)

Safe
Affordable
Gentle
Non-Surgical

Visual Freedom from glasses.

Mid-South PCM(tm) Group, P.C.
J. Mason Hurt, O.D.

Bartlett, TN 38134
901/382-7803
800/947-4257

Page 2 thru 4
What is PCM(tm)?
Image being able to easily read an alarm clock without your glasses, see

street signs clearly, or participate in sports without lenses of any kind ... These are just a few of the freedoms people are enjoying through Precise Corneal Molding(tm) PCM(tm).

PCM(tm) is a safe, gentle, affordable, and non-surgical procedure that dramatically improves natural vision by reshaping the front of the eye, the cornea, with scientifically shaped molds. Because the procedure is non-invasive, PCM(tm) has provided thousands of patients with better vision without the risks or complications of surgery.

Nearsightedness, farsightedness and astigmatism occur when light rays [A entering the eye through the cornea focus incorrectly. PCM(tm) utilizes a series of prescription eye molds to reshape the cornea much like orthodontists use braces to straighten teeth. The result is a gradual correction of vision, enabling patients to see clearly throughout the procedure.

The PCM(tm) procedure involves a series of thorough examinations by Dr. J. Mason Hurt, recognized in the medical community as an expert in PCM(tm), and a series of mold modifications. The benefits are realized[A in weeks or months, depending on the severity of vision problems. Retainer molds will be used on a limited basis to maintain the new shape of the cornea.

Since 1962, PCM(tm) and its predecessor, Orthokeratology, have been used to help pilots, athletes and others requiring unaided vision. Now, new research developments such as computerized corneal topography and new mold designs and materials have established PCM(tm) as the eye care trend of the future.

The Safest Option

In contrast to Radial Keratotomy and laser surgery, PCM(tm) does not require injury to the eye, resulting in glare-inducing scars. There is also no disruption of vision as eyesight improves.

PCM(tm) for Children

One of the most exciting uses for PCM(tm) is controlling nearsightedness in children. Unfortunately, nearsightedness is a progressive condition, which is why 75% of patients who are nearsighted must periodically increase their prescription. For example, only 4% of 8-year-olds are nearsighted, while over 30% of the general population is nearsighted.[A PCM(tm) prevents deteriorating vision and even reverses it.

Proven Safe Results

PCM(tm) is highly effective in correcting nearsightedness, farsightedness and astigmatism. Even severe cases find great benefit from PCM(tm).

University research studies have shown corneal molding to be safe and effective. These studies include the: University of Houston College of Optometry (5 years), University of California at San Diego Medical School (7 years), University of California at Berkeley College of Optometry (3 years), and Pacific University College of Optometry (5 years).

Page 5

Patients See The Difference

"I shifted from soft contact lenses to PCM(tm) and I can see 20/20 when I take them off!" -- T.K.

"I have been through the program and I am very happy with the results. I'm taking my daughter in for Precise Corneal Molding(tm), too!" -- A.S.

"I am very happy with PCM(tm) and would recommend it with no reservation." -- D.M.

"I never realized how precious the gift of sight was until I underwent the PCM(tm) procedure." -- A.S.

Compare!

PCM(tm) is a safe, gentle, affordable, non-surgical alternative for wearers of glasses.

	<u>_Surgery</u>	<u>PCM(tm)_</u>
Age as a limiting factor	Yes	No
Reversibility	No	Yes
Loss of work time	Yes	No
Worsening of night vision	Yes	No
FAA and military approval	No	Yes

PCM - Precise Corneal Molding

For those who are interested in my progress:

I saw Dr. Hurt yesterday. This is how the office visit went.

I am taken into an examination room. Patti asks if I am still wearing the molds 18-20 hours a day. I say no, I am only wearing it about 12 hours and I am not sleeping in them. She turns out the lights and asks that I look at the wall chart. I can not see the 20/20 line, just the line above it. (I have my molds in while this exam is taking place.) I now cover my left eye. I can only see the 2nd line from the top. (The wall chart is projected onto the wall.) I now cover my right eye. I can see 20/20 with my left eye.

Note: When the molds are off, I can see better with my right eye than my

left eye. When the molds are on, it is the opposite.

I then go and take the molds off. I enter the next examination room. I do not know what the machines are, so I will describe the procedure instead.

1) I look into this machine (with my eyes closed at first because it has a bright light). I open my eyes and blink once. (Each eye is done individually.) Patti then puts a yellow dye into my eye and I do the same procedure as above. The computer monitor now has four eye images.

2) The next machine has a small cone that I look into. (This machine replaces another that has a large cone.) A map is taken of each eye.

Note: Patti is very impressed with the results from the previous visit. She shows me the maps and there is a significant difference.

3) The next machine I look into has a picture of a Hot Air Balloon in it. The picture comes into and out of focus.

I now go into the doctor's examination room. He looks at the computer monitor with the images of my eyes. He uses this to make sure that the molds are moving and sitting correctly on my cornea. I then look at the wall chart thru some device that he adjusts. Then he look at the maps of my eyes and seems to be impressed by them. He basicly says that next month I will be going on some kind of wearing schedule different than what I am currently on. I think this is a positive sign since he usually says that I am improving and to see him in a month.

Conclusion:

Since some members of this group mentioned bilberry, I started taking it with Super Blue Green(tm) algae. The bilberry should help my eyes and the algae should help my health.

I have been doing PCM since 15 Jan 1995. I had significant improvement the first week I was in the program. I could not tell the improvement since I still could not see without my contacts. Over the summer improvements came slow even though I changed molds at least three to four times. I do not know if I can credit the bilberry for the latest improvements, but I sure am not going to discount the fact that I have been using it and results have happened.

As far as the algae is concerned, I have fewer sinus problems. I can now sleep at night without waking up sneezing at 2am. I am the kind of person that will suffer before I take any kind of manufactured chemical.

Aspartame Section:

I have also eliminated aspartame (Equal(tm)) from my diet. I usually don't drink diet drinks, but when I need something cool to drink I would pick up a diet drink if nothing else was available. I no longer do that. I also suggested to my wife that she quit drinking diet drinks. She did and noticed that her joints no longer gave her pain. She is a doctor and has to travel to about 3 hospitals and round on her patients. She has to do a lot of walking.

She also bought some vitamins for our children the other day. I looked at the label and discovered that the number one ingredient was aspartame! We did *not* give this to our children. If you are trying to eliminate aspartame from your diet beware of anything labeled sugar free. I have found it in gum, jelly, and cough drops.

Your for better health,

RobJB

Subject: Re: Ortho-K, Dammit!

If you are with the FDA it is a custom, theraputic or corrective, Contact lens. The use of the designs described was an undocumented application of rigid contacts which was taught and scientifically studied prior to 1962. (In fact 1880's was first reported in France)

The reverse aspheric back surface design is very different than a Contact Lens.

Almost all US contact lens designs are based on following exactly the surface contou of the eye with a spherical shape back surface contact. In fact the surface of the eye is not spherical but multiaspheric. So the doctors must bridge over the central area to get a "lens" to center. A corneal mold uses the fluid forces to reshape the central cornea. The same shape change from RK, PRK, Corneal Molding, ALK, or Corneal Rings will improve vision.

A -1.00 Dioptor eye needs a "shape" change of 0.20 mm. A very small amount produced a significant visual handicap for the patient. Night wear of a corneal mold will easily produce up to 0.40 mm change. Gentle, safe, reversable, effective correction of a vision handicap.

The new corneal molds use a CNC lathe to put multiaspheric curves on the back surface of the molds. Several computer designs are custom applied to each patients needs. They are made out of FDA approved materials and methods. All night wear molds are "extended wear" rigid materials.

I find the best case has 2 hours a week wear, the worse case only gets functional vision for 6 hours after removeal of the molds. The patient can drop out and have "surgery" at any time. After all refractive surgery, Corneal Molding can be applied to "tune up" and smoothe irregular astigmatism, nearsighted, or farsighted vision. After 10 years all "surgery" patients may require a "tune up" due to the fact that the original cause for surgery, myopia, will get worse. The Orthokeratology molds cause myopia to stop progressing. Now out 20 to 30 years, these patients only replace molds due to material failure.

Thanks for the question.

30 Nov 1995 Checkup

Background:

PCM - Precise Corneal Molding (Corneal correction without surgery.)
Started Jan 15, 1995 with about -5.0 diopters

Current:

Wear schedule: 18 hours, I might sleep in them once a week.
Right mold sticks to eye at the end of the wear schedule, possibly because eye has taken on too much of the shape of the mold.
Decreased sight in both eyes while wearing the molds since I first started wearing this set of molds.

Checkup:

Nothing new, molds are continuing to shape my corneal. The top part of my cornea is flattening out and moving toward the center. I was told to think of the cornea as a balloon. When you flatten the top part the bottom part bulges. This bulge is moved to the lower part of the cornea, out of my line of sight and the flatten area moves into view. The checkup went as described in the last report. At the conclusion of my checkup, I tried to put my molds back on. But, I broke my right mold.

Mold Replacement:

This will be the second time I have had to replace the molds thru a mishap. The first time I dropped it in the sink and it went down the drain. I now have a pancake sized strainer that goes into my sink. I only replaced the lost mold, not the set, which I discovered was a mistake. My eyes no longer focused correctly together. I tried to live with it for a week, but had headaches. I went back and asked to have the left mold changed. Another week went by before I received the left mold. I was not happy for those three weeks. Whenever a mold is replaced, it is updated. This time I insisted that both molds be replaced. In the mean time, I was given a mold that I had previously used in my left eye (it was close to what I needed). Actually, I can see better with it than the right mold it is replacing. I also can see better in my right eye than my left eye with both molds on.

Helpful stuff:

Bilberry - keep eyes healthy which helps tear formation. This keeps the molds moving and working so that the end result is faster.
Super Bluegreen Algae - cuts down on allergies, keeps sinus open, general health promoter.
Calcium - Cold killer.
Aspartame (Equal(tm)) - Don't even think about it!

Patient Interviews (brief encounters):

1) Female, in her 20's, another doctor recommend she try PCM. Started about two months ago at -2.75 diopters. Astigmatism gone the first two weeks. She became allergic to contacts. She has noticed a good improvement in her vision. She doesn't like it when a speck of dust gets behind the mold. She must take the mold out to get rid of it. I also have experienced the same problem.

2) Female, in her 20's. She said that if she must wear contacts, she might as well have them do something. She said once you have surgery, you can't wear contact (mmm.., don't know about that). Her brother has had eye surgery three times to try and correct his eyesight. He still wears glasses.

3) Female, in her 30's, she has been wearing the molds for about one and

a half years. She started at -7.0 diopters. She has gone through lots of molds.

4) Male, in his 30's, he gave up on the program and is wearing glasses full time.

Disclaimer:

I am not a doctor or a reporter. The interviews were obtained through casual conversation and observation.

My next appointment is in two months. I will be picking up my new set of molds on Monday.

Have a happy holiday,
RobJB

Chromalux bulbs, which are screw-in replacements for regular incandescent bulbs, are available at many health food stores (at least in San Francisco and Santa Fe) and from several health-food mail order companies.

These are incandescent bulbs that use a light-blue coating on the outer glass and a mix of rare metals in the filament to produce a full-spectrum output. The advantage they have over fluorescents is that they work in any incandescent fixture; the disadvantage is that they can't generate UV (or so I've been told), so they're not as "full-spectrum" as the fluorescents. They come in 60, 100, and 150 watts, but they don't produce as many lumens as regular bulbs, so you should go up one size to keep light output constant (eg. replace a 60-watt regular bulb with a 100-watt Chromalux).

They cost about \$7 each, but claim to last four times longer than ordinary bulbs, so the price isn't too out of line. I've been using them for over 2 years. I'm not sure about any therapeutic benefit, but the light looks better (ordinary bulbs now look disgustingly yellow to me); my wife, who has a poetic bent, says the light from them is like moonlight.

My favorite source of full (or at least full-er) spectrum lighting is halogen lamps. One of them can light up a whole room very well. You can dim them without causing annoying flicker. They cost about US\$50 at discount department stores. The light is very "white" and uses less energy than incandescent. It gets my vote as the best artificial light source.

> Hi People.
> Rumor has it that the company that I work for *might* purchase some
> full spectrum lighting for us. Any ideas were we could find lamps/
> lightbulbs? Prices? Etc.?

If you're in a large city, you should be able to find the Chromalux

incandescents at health food stores, and the Ott (or similar) fluorescents at health food stores or electric supply or lighting stores. Also Ott has an 800 number for orders, don't have it offhand but 800-555-1212 should be able to tell you (they're somewhere in Florida).

Chromalux bulbs cost about \$7.00 each, although you can probably get a deal if you buy a bunch. They do last about 4 times longer than regular incandescents, so the price isn't as bad as it first seems. They don't produce as much light as regular incandescents, so you need to get slightly higher wattage for equivalent lumen output.

I don't know how much the Ott tubes cost, but the bulbs that screw in to an incandescent fixture cost about \$33, vs. about \$25 for the non-full spectrum. As I recall (I could be wrong, ask them) the smaller screw-ins don't provide the UV that the tubes do, so they're not entirely full-spectrum.

BTW 1: The quality of the light produced by Chromalux vs. Ott vs. other full-spectrum fluorescents is different. You might want to get some samples to try before you commit to a large order.

BTW 2: GE claims to have a full-spectrum incandescent, but it looks like all they did was put a blue coating on a regular bulb to cut down the yellow. Chromalux does this too, but also adds neodymium (sp?) to the filament to change its light output spectrum.

BTW 3: Something better than full-spectrum, if possible in your situation, is skylights. Not only are they better than full spectrum in matching natural sunlight :-), but they don't require electricity so there's a cost saving over time. There are skylights available now that use some sort of a lens system, so they can bring in a huge amount of light through a small hole in the roof.

Hello Vic and I_SEE group:

I was happy to read of your discoveries of voluntary accommodation. My findings are very similar. I have a neat gadget called a contactscope - a device that allows you to see your own iris and pupil of one eye at a time, under great magnification. I have my patients look at their pupil and this sets in motion the accommodative response, and they get feedback by seeing the pupil getting smaller. They then have to relax and watch their pupil becoming larger. This becomes a fun game and it gives them the feedback you described in your article. If any of you would like this device (costs around \$20) , it is part of our catalogue products and can be obtained from us. There is a \$5 shipping and handling fee to post the catalogue.

Just reading an interesting account of a French Canadian Behavioural Optometrist viewpoint of myopia.

A few juicy quotes:

Myopia has become a social curse....The Optometrist may be the instigating trigger of a crippling process...It is not because of one's eye that one becomes a myope. It is because of one's brain....Convex lenses at least retard the process of myopia.

Armand R.Bastien, O.D. from a compedium of papers on Myopia, published as Curriculum 2 Vol., 59, No 1 October, 1986 by the Optometric Extension Program.

All the best, Robert-Michael.

...snip...

I have ordered this system and it comes with a very informative booklet and three sets of glasses. You guessed it (+1.00, +2.00, & +3.00). The basic key to the whole program is to take your glasses off and hold some regular text (like a newspaper) at a distance so that it just SLIGHTLY blurs. After about two minutes when the text starts to clear up push it slightly out of focus again. The only purpose of the glasses is to bring the 'blur' zone to a convenient distance for reading starting with the +1.00 lens. I myself do not need the glasses yet because I cannot see the text at an arms length.

This program has worked a little for me so far. I used to hold text 8 inches from my eyes in order to see it in focus. Now I can hold the same text about 14 inches away and still see it as clear as ever! I have been doing these exercises for about a month. The only real side effect of the program is that I had a few headaches (eyeaches) the first week, but I do not get them anymore. The book suggests practicing for 30 minutes to 2 hours a day while reading a book or similar using a 10 minute practice/10 minute rest cycle. It also recommends not wearing your regular prescription glasses when at all possible, except when safety requires it. It is a reduced correction system, but you have to buy the new glasses from your eye-doctor as your eyes improve.

As you can see there is not much to the 'system' itself, and one could actually have some success just following what I've said above, however, I am not an eye-doctor, so if it would make you more comfortable having all the information on-hand, then I suggest purchasing the kit.

Deryck S. Schnee -- derycks@clark.edu

P.S. Does anyone know where minus glasses can be purchased aside from the optometrist? (I realize it may be illegal, so... that brings me to question #2) Anybody know of an eye-doctor in the Portland,OR area that supports vision therapy type practices?

Greetings from sunny British Columbia. I have checked with Alex regarding posting information about some training programs I 'll be offering this summer and he said: *>Post away! If you want to talk about some of your products, that's OK too!*

Because of your keen interest in improving your vision and helping others to see more clearly, I'm extending a personal invitation for you to come and spend a week with me this summer. You will learn the basic program of Integrated Vision Therapy in order to heal your own eyesight and assist others as well. This special training is being held from August 21st to 27th, 1995.

Whether your interest is purely to improve your own vision, help others, add to your existing career or start a new one, this one-week intensive program is a wonderful opportunity to deepen your self-healing journey.

The training is being held at my INN-SIGHT, Centre for Wellness and Vision on the Sunshine Coast (1-1/2 hours from downtown Vancouver in B.C. Western Canada). The program is set-up in such a way that we meet for 3-4 one and a half hour teaching modules per day and then you have the time to review and practice new ways of seeing on your own in a natural woodland setting or at the ocean nearby. Gourmet vegetarian food and comfortable shared accommodation in our bed and breakfast facility at INN-SIGHT is provided. If you wish to talk in more detail about the upcoming training, please e-mail and I will behappy to give you more details.

A report I just received may be of interest to you.

Researchers at the UK Bristol Eye Hospital have developed a computer system that uses eyes "as a guide to the physical and mental condition of patients." Dr. Demetrious Papakostopoulos and Dr. Christopher Dean Hart say they have the tools to probe the brain's mechanism. The computer system is called the pupillometer, which digests an infra-red videw of a patient's eyes, rendering rates of pupil expansion and contraction into a graph while lights are being turned on and off. "There is no systemic disease known to man that does not show some manifestation in the eye.", Dr. Hart said this month. "The eye takes light's physical energy and transforms it to a currency the nervous system understands", Dr. P said.

All the best, Robert-Michael Kaplan. O.D., M.Ed., FCOVD.

P.S. A little bit about myself.

I am a doctor trained in optometry, visual science, education and psychology. I was a professor of optometry for ten years doing research on vision therapy. Due to my frustration with conventional vision care, I developed a consumer oriented program of improving vision fitness, which is in my book Seeing Without Glasses and my new book The Power Behind Your Eyes. I am a photographic artist a father of a 5 year old, live in paradise, fish, love to share my wisdom, and am becoming a net lover.

I wondered if anyone has any experience with pinhole glasses. Have they used them, how effective did they seem, where can I purchase some, are there different kinds?

I currently use a headpiece when working at the computer as a visual clue to keep my head aligned with where I am looking. I can definitely notice the difference when I use this versus not. My vision is less blurry when I finish the computer work than it would be normally. The headpiece looks weird though so I only use it at home, not at work.

I was thinking that pinhole glasses might offer some of the same benefits.

Status: RO
X-Status:

The headpiece I use at the computer is actually quite simple. It is a piece of thick wire -- about clothes hanger thickness -- that is bent into a circle about the circumference of one's head. Then from the front of this circle bend the wire so a piece comes down straight perpendicular to the circle. Put the wire on your head and align the straight piece so it comes down directly in front of your nose.

I hope that description is understandable. It's sort of like wearing a miner's or spelunker's head lamp without the lamp. And from where the lamp would be a piece of wire extends down about 10 inches directly in front of your nose.

You can check the alignment by closing first one eye and then the other and making sure the images from each eye of the piece of wire hanging down are equidistant from the tip of your nose.

What you must try to do then is to only look at things that are between the two images of that piece of wire. This is obviously not as focused as pinhole glasses but it does seem to help.

I can't take credit for this invention. I got it from Tom Quackenbush who runs eye improvement seminars in San Francisco.

His organization is called the Natural Vision Center.
P.O. Box 16403
San Francisco, CA.
415-665-2010

If anyone can't figure out what the headpiece looks like let me know and I'll try to explain it better or upload a picture (if I can figure out how to do that).

X-Status:

Hi Alex,

I'm back..had a wonderful time..lots of exercise and little reading and that only for pleasure. Happy for you to see so much enthusiasm/response for your isee net. Very busy now, catching up for missed days but I scan the letters and will respond when i can. On the long eye of myopia...it is almost always (99.9%+) due to a longer eye..this has been shown again and again since the advent of ultrasound..a tool not available to Bates, or to those who think its a stuck ciliary muscle...though in the early stages of myopia, it can begin as a stuck ciliary muscle..hence people should be cyclopleged to eliminate this variable especially before Bates training because noone would be impressed if Bates training just got the ciliary muscle to relax...because it can also occur by doing nothing!! The longer eye could still be due to the extraocular muscles placing tensile stress on the sclera (the outer coat of the eye that gives the eyeball its shape) which is then weakened and can result in the elongated eye typical of myopes.. Raised IOP, intraocular pressure, could also cause the eyeball to get bigger. Finally, something about the quality of near environments..the vergence of light perhaps..could cause the retina to signal to the sclera to grow...in chickens who have been experimentally made myopic by putting a pingpong ball device on their eyes..have shown increased production of proteoglycans..a growth protein molecule. In humans, in high myopia, the sclera actually thins..its called staphylomas when its gets bad..and this suggests that thinning is the cause.

For all of you interested in myopia development, I am a grad student at Berkeley and would love to make some important measures on people who are reducing their nearsightedness to put this therapy on the map and hopefully in the future make it available to kids in school, much like gym or advanced mathematics is available. Would be interested in hearing from you, especially if you live in California or plan a trip where I could spend a few hours making some measurements on you. Thanks!

Lynn

Francis A. Young et al, "The Transmission of Refractive Errors within Eskimo Families," American Journal of Optometry and Archives of the American Academy of Optometry 46, no. 9 (September, 1969).

Donald S. Rehm, in /The Myopia Myth/, summarizes:

:The Eskimo population was a unique group to study in that the older
:generation was essentially illiterate and had never gone to school, while
:the younger generation was required to attend school.
:[...]
:Of 130 parents, only two showed any myopia. One had 0.25 diopters and one

:had 1.5 diopters. All the rest had refractive errors between 0 and +3
:diopters. In other words they were somewhat farsighted, which can be
:considered normal.

:
:Regarding the children of these nonmyopic parents, a totally different
:picture was found. Fully sixty percent of the school children examined
:showed measurable amounts of myopia. Of the fifty-three individuals who
:were between twenty-one and twenty-five years old, eighty-eight percent
:were myopic. There was a beginning of myopia at about age ten, with a
:steady increase in the proportion of the children showing myopia up to
:ages twenty-one to twenty-five years.

A little comment: look at the title of the article. I imagine he couldn't
have published this study if he called it "Evidence for school-induced
myopia in modern Eskimos," which it really should have been called.

Hello Rene

Keep me posted on your studies. I feel your common interest in
physiological optics downunder to be very encouraging.

To all I_See members. Dr Thomas Norton of the University of Alabama
presented a public lecture on laboratory studies in myopic development. He
concludes that for his model an active emmetropization or "normalization"
occurs. He was able to create myopia, hyperopia and normal in genetically
equal subjects.

The hyperopia present at birth causes the eye to grow longer until a "normal"
length is reached. If hyperopic glasses are worn the eye prematurely stops
the growth. Thus remaining shorter and more farsighted into adulthood. If
myopic lenses are worn which are stronger than needed for vision, the eye
contiunes to grow to the point of becoming longer than normal. The
dependence to glasses is shown to occur in these animals. He can also deprive
the animal of normal peripheral vision to develop myopia on the side which
did not have normal stimulation.

Dr Rene > Feels that we must caution that the subjects were not human and the
myopia corrections were much stronger than would be prescribed.
The lecture was attended by the senior faculty at UAB. It does represent a
change in the core thinking of Optometry that myopia is not a 100% genetic
disease. Several new drugs were discused that were recently patented in the
US for myopia prevention. No specific treatment options were presented.

I have requested a transcription and will post it on I_See when received.

Dr Norton has done a lot of work with tree shrews, and chicks, I believe. In these animals, there is a critical period where these animals can be made myopic or hyperopic by modifying their environment (eg with translucent occluders or spectacle lenses). This is in the animal's very early life, while the eye is still developing its structure. It is truly fascinating work, and it should have benefits to us all. However, to extend these theories to humans, particularly adults, must be done with caution. It is difficult to get reliable results with higher primates, for example. In addition, even a very small period of "normal" vision in these animals will prevent the ocular changes from occurring. In fact, chicks only need 30 minutes to maintain the normal emmetropic condition. There is quite a body of evidence that form deprivation conditions may cause myopia in young humans as well, for example in medical conditions or injury which fog the image on the retina, or even retinal diseases which means that the eye is unable to process the image falling on the retina.

Here's a little review I am in the process of writing, fyi.

Evidence of form deprivation myopia in humans.

copyright where appropriate, Rene Malingre 1994

There is little doubt that there is a system that monitors the quality of the retinal image in humans, as evidenced by the formation of amblyopia in the eyes of young children who have experienced unusual visual stimulation. Amblyopia may be caused by optical blur, as in anisometropic amblyopia, or by occlusion or distortion (partial or complete), of the retinal image by factors such as congenital cataracts, corneal opacities, or even prolonged occlusion of the previously normal eye in amblyopia therapy. A decent retinal image is vital for the development of normal retinal (especially central) anatomy and function, and for the formation of appropriate higher neural connections. Evidence from animal and human studies have shown that the quality or clarity of the retinal image also adjusts the growth of the eye, and is therefore at least partially responsible for the formation of refractive errors.

Degradation of the retinal image has been found to cause myopia in a variety of experimental animals, since Wiesel and Hubel(1) introduced the monocular form deprivation paradigm in monkeys in 1977. Studies in chickens,(2-4) cats,(5) tree shrews,(6) marmosets,(7) and monkeys(1, 8, 9) have supported the view that the functional impairments resulting from monocular deprivation of form vision in the early stages of life in animals can lead to extreme axial elongation and growth. Interesting, total deprivation of form does not appear to cause the same ocular changes; altered retinal input is needed to cause the ocular changes, rather than total lack of stimulation.(10-12) There is a substantial body of evidence suggesting that local mechanisms play the primary role in mediating axial elongation under form deprivation conditions. Perhaps the most startling evidence comes from Wallman et al.,(3) who found that when white translucent occluders were applied to either the nasal or temporal side of developing chicks' eyes,

only the deprived section of the eyes became myopic. Optic nerve sectioning,(13) ciliary ganglion removal,(14, 15) destruction of the retinal ganglion cell layer,(16) and removal of the striate cortex, does not prevent lid suture myopia, although greater variability in refraction occurs under these conditions. Schaeffel et al.(17) demonstrated that optical blur will cause refractive error in developing chicks. Chicks are able to detect and respond to both the sign and magnitude of defocus by increasing or decreasing the growth rate of the vitreous chamber so that the retinal blur is reduced. All of these effects can occur if the optic nerve is cut, although not as consistently, implying that there may be higher order neural input to the process. Negative lenses will cause myopia, and positive lenses will cause hyperopia such that the eye-lens combination tends to bring distant objects to a focus on the retina. Wildsoet et al.(18) have shown that atropine reduces both form deprivation induced- and lens induced myopia in chicks, suggesting a similar mechanism underlies both processes, with atropine acting via a non-accommodative mechanism.(19)

Case reports of ocular conditions causing a reduction in form vision in neonatal humans support the hypothesis that form deprivation in humans can result in axial elongation and myopia. These include monocular conditions such as retrolentia fibroplasia, persistent pupillary membrane, vitreous debris, ptosis,(20)(21-24) cataract and trauma, which are associated with a consistent, significant myopic shift in the affected eye when compared to the fellow eye, and binocular visual anomalies, such as retrolentia fibroplasia, optic atrophy, macular dystrophy, and congenital cataract in which the eyes are significantly more myopic than eyes from normal controls. The major difficulty in interpreting these data is the fact that the cases are uncontrolled, and case selection may be biased. The ocular conditions may in themselves cause or be associated with axial elongation, through non-visual mechanisms.

In conditions where there is a fixing eye and a non-fixing eye, there tends to be a shift towards myopia in the fixing eye in a large number of circumstances. These include monocular corneal scarring, where the scarred eye does not undergo the same myopic shift as the affected eye, whereas if both eyes are scarred, both eyes tend towards myopia.(25, 26) Congenitally ptotic eyes often show a significant increase in myopia in the affected eye,(27, 28) yet normal binocular vision and acuity still develops in a large proportion of cases.(27) This may mean that the system mediating correct ocular growth is very sensitive, perhaps more sensitive to deprivation of form than the system mediating correct neural development and acuity. O'Leary and Millodot(27) hypothesised that eyelid closure per se caused myopia, rather than degradation of form vision, and in a survey of two samples of myopes, myopes reported sleeping more than the non-myopes they lived with. A number of studies have investigated the relative change in refraction of fixing and amblyopic eyes of strabismics.(29-31) These studies have found that the fixing eye tends to show a myopic shift in refraction (similar to normal eyes), while the non-fixing, amblyopic eye tends to have a fairly static refraction. Almeder et al.(32) found that most cases of early childhood anisometropia disappeared later in childhood, leaving a very low incidence of persistent anisometropia in children. The authors proposed that adult anisometropia is the result of, rather than the cause of, amblyopia. While the fixing eye in constant strabismics undergoes emmetropisation or myopisation, it has been found that there is little relative change in refraction between eyes in alternating strabismics.(33, 34) A Russian study has a high incidence of unilateral myopia in a population of industrial monocular microscope users.(35)

The evidence presented so far applies to young, developing humans and animals. The fixing versus non-fixing eye studies suggest that myopia occurs when the visual system is actively trying to obtain useful

information from a form deprived eye, whereas refraction remains static when information is not being sought from a form deprived eye. This hypothesis requires higher order neural input to myopigenesis. It appears that lowered and altered retinal activity is related to form deprivation myopia.

The conditions under which form deprivation myopia is apparently produced in humans are quite extreme. Whether form deprivation conditions can produce myopia in otherwise healthy eyes in childhood and adulthood remains unanswered. What conditions could cause form deprivation in adults?

Many studies have shown a correlation between educational level or amount of reading and fine near work and myopia.(36-47) Josh Wallman et al.(3) hypothesised that printed text may represent a form deprivation condition in humans. Printed text may provide adequate stimulation for the central retina, but an impoverished stimulus condition for the rest of the retina. This is because printed text contains mainly high spatial frequencies, which are unresolvable by the peripheral retina. If form deprivation myopia is mediated by retinal activity, the lack of stimulation of the peripheral retina may induce ocular growth. Wallman extends this further by pointing out that printed text has a much smaller range of luminances than a typical scene, and it is achromatic. Both factors would further reduce the degree of retinal activity, including the central retina. As form deprivation in experimental animals appears to be spatial frequency dependent,(48) it may be that even the central retina does not receive adequate stimulation by printed text.

David Goss in 1988(49) suggested that a greater than usual lag of accommodation would degrade the retinal image during near-work activity such as reading, and may lead to form deprivation myopia. This hypothesis has some supporting evidence, with the finding that both early-onset myopes and late-onset myopes have a greater lag of accommodation, or have a reduced accommodative response to blur.(50, 51) Juvenile myopes with a nearpoint esophoria progress at a faster rate than those with orthophoria,(52, 53) although the difference in rates is as small as 0.07 D/year.(52) Goss(54) found that juvenile emmetropes who became myopic before the age of 15 were relatively more esophoric and had a lower positive relative accommodation before they became myopic than emmetropes of the same age that remained emmetropic. While it may be argued that the accommodative insufficiency and esophoria found in myopes and pre-myopes may be due to an alteration of the accommodation-convergence relationship because of a change in refraction, Goss'(49) hypothesis can explain the limited success of efforts to control myopia through the use of bifocals.(52, 55-58) Goss and Grosvenor(59) reanalysed previous bifocal studies(52, 57, 58) and discovered that bifocals appeared to be effective only in those subjects who had a near point esophoria through their distance refraction. Near esophores may reduce their accommodative response, thereby having a greater lag of accommodation, in an effort to reduce their convergence and improve their ocular comfort. When the accommodative demand is reduced with a near addition, the esophoria is reduced, and the subject's accommodative response may be more accurate, thereby eliminating the form deprivation condition of blur.

>

>The hyperopia present at birth causes the eye to grow longer until a="normal" length is reached. If hyperopic glasses are worn the eye prematurely stops the growth. Thus remaining shorter and more farsighted into adulthood. If myopic lenses are worn which are stronger than needed for vision, the eye continues to grow to the point of becoming longer than normal.

When normal vision returns, the changes also tend to reverse, if the eye is still developing.

The

>dependence to glasses is shown to occur in these animals. He can also deprive the animal of normal peripheral vision to develop myopia on the side which did not have normal stimulation. Dr Rene > Feels that we must caution that the subjects were not human and the myopia corrections were much stronger than would be prescribed.

My biggest caution is that the experimental animals are very young. If a child of mine was quite hypermetropic, and needed spectacles for an accommodative strabismus, I wouldn't want to fully correct the hyperopia until he or she were five or so, after any emmetropisation mechanism had time to work. Of course, if a full correction were needed to keep the eyes straight, I would prefer my child to have normal binocular vision, even if it meant that he or she remained fairly hyperopic. We just don't know what, or if, emmetropisation mechanisms occur in humans. Many people have argued persuasively that the large percentage of emmetropes we have as a population is purely a consequence of normal growth of ocular components, without any need for a coordinating mechanism. My gut feeling, however, says that there is a mechanism. However, I do not believe that an eye that is already myopic can be pushed back to emmetropia, purely because of the nature of the changes that cause myopia, and the changes that would have to take place to get rid of it.=20

=20

>The lecture was attended by the senior faculty at UAB. It does represent a change in the core thinking of Optometry that myopia is not a 100% genetic disease. Several new drugs were discussed that were recently patented in the US for myopia prevention. No specific treatment options were presented.

I doubt whether any optometrist I know believes that myopia is 100% genetically determined. It does play the biggest role, however.

The drugs are probably muscarinic antagonists, drugs which block specific types of neural, or neuromuscular transmitters. For many years, atropine (a non-specific anti-muscarinic drug) has been used in an attempt to halt or prevent myopia, with some arguable success. The paradigm stated that excessive accommodation causes myopia. Atropine causes long-lasting cycloplegia - the eye cannot focus no matter how hard it tries. Recent animal studies have shown that atropine can prevent the form deprivation and lens-induced myopia. However, in chicks at least, this is NOT due to its action of cycloplegia, because chicken ciliary muscles are striated muscles, and have different neuromuscular transmitters. In other words, chicks treated with atropine accommodate normally. There are a number of types of muscarinic receptors, however. Some are in the retina. It has been postulated that atropine, and other more specific anti-muscarinics, prevent the release of scleral growth factors, thereby

stopping the eye from becoming myopic. However, even more recently, it has been considered that the doses of the drugs used to prevent the myopia might be high enough to be toxic, and prevent the growth through a poisoning of the cells responsible for scleral remodelling. Only time will tell. In countries with few restrictions on medical experimentation, some limited trials have begun on the use of some of these specific anti-muscarinic drugs, which affect the retinal receptors, but do not cause cycloplegia.

>environment.

Distance lenses hazardous to your eyesight?? They make you SEE, Alex!
One point you have missed is that the lenses overcorrect the animals;
the eyes of these very young animals compensate for the overcorrection;
they don't keep going past the point of compensation! So, your argument
is flawed.

Also, cautious optometrists should make their patients -- especially the
young ones -- aware of these laboratory studies. This could help them
if one of their patients ever decides to sue for not warning of the
possible side-effects of the treatment -- standard practice in all
other areas of medicine.

I do not consider the prescription of spectacles for myopia treatment.

They are simply a visual aid. They certainly do not "treat" myopia, they simply enable the wearer to see distant objects clearly. There is no evidence they make matters worse, either, in humans.

See, for example:

1. Goss D. Overcorrection as a means of slowing myopic progression. American Journal of Optometry and Physiological Optics 1984;61(2):85.

>It seems to me that the laboratory studies were designed specifically to
>be inconclusive.

Get a life, Alex! Your conspiracy theories reflect very poorly on you. Alex, the world ISN'T flat, and credit card companies aren't conspiring to rid the world of real money in order to fulfill a bible prophesy.

>In spite of this, and in spite of the ho-hum reaction by
>optometrists to the studies,

I would hazard a guess that most optometrists haven't made themselves aware of the studies. It's pretty recent work, and only applies to neonatal animals at this stage.

>the studies are entirely consistent with the
>hypothesis that refractive error in otherwise healthy eyes is 100%
>controllable by manipulating visual stimulus.

Another Alex sweeping generalisation. The results aren't as clear cut as you would obviously like to believe. See the following article for evidence for inherited characteristics, for example:

Zadnik K, Satariano WA, Mutti DO, Sholtz RI, Adams AJ. The effect of parental history of myopia on children's eye size. Journal of the American Medical Association 1994;271(17):1323.

However, the results of the studies are fascinating. I am sure they will have application to humans. However, just because something works in one animal doesn't mean it will work in another.

Alex, think a little kinder towards your fellow human. There are no world-wide conspiracies in physiological optics. Science doesn't work that way.

Rene

> "Every child who wears glasses for myopia gets worse." Think about that
> one for a while. The kid wasn't always myopic. The axial length grew to
> a point where the image of a distant object fell in front of the retina.

Now right there that's an assumption that may or may not be true. One theory of myopia development is that myopia always starts with "pseudo-myopia", that is, a temporary over-contraction in the focusing

muscle brought on by stress, illness, too much reading, or what have you. That is, things are out of focus not because the eye is too long, but because the focusing mechanism is out of control.

> Don't you think the same process that caused
> the myopia in the first place would continue anyway? As I said, glasses
> are not a treatment!

Not necessarily. It may or it may not. According to one interpretation of the data from laboratory animal studies, here's what happens.

1. The kid's lifestyle does not change, in which case the eye is still picking up blurry images. This causes "form-deprivation-induced" elongation.
2. The kid puts on glasses, in which case things clear up, but the eye, being at first of normal size, now adapts to the minus-lens, becoming longer in order to make close work easier with glasses on -- "lens-modified emmetropization".
3. The kid starts walking straight, looking at the treetops, getting lots of fresh air and sunshine, and watching the clouds go by. Those pseudomyopic eyes spring back into life.

Now I know what you're going to say. You're going to say that eye doctors use special drops during an eye exam, which eliminate functional myopia. In response, I say that these drops may reduce, but often enough do not completely eliminate functional myopia. Complete elimination of pseudomyopia takes several days of atropine.

What I'm getting at is this: with constant wear of distance lenses, myopia doesn't have a chance in the world of improving, because the eye has absolutely no stimulus to do so. Myopia is actually stimulated to get worse, because the demand to focus INCREASES AT EVERY DISTANCE. If you don't wear glasses, you have a chance of improving your myopia, although it may continue to get worse if you don't learn how to use your eyes correctly. But without glasses, myopia never gets as bad as it does with glasses.

Incidentally, just because a "critical growth period" has been passed does NOT mean it's too late for you to develop towards normal vision. Exercise produces organic changes in the heart, lungs, and muscles, for example, at any age. Glands in the body are known to grow and shrink through life. There is no reason to assume that changes are impossible in the eye. In fact we know it can get worse -- why can't it get better, too? Just give your eyes a chance!

--Alex

PS I would really like to go on and on about the doublespeak involved with the official definitions of words like "acuity" and "correction" but I understand most people find such discussions tiring, so I won't.

From: Alex Eulenberg <aeulenge@indiana.edu>
Subject: Interpreting laboratory studies
Status: RO
X-Status:

I wish to thank I_SEE subscribers Jim Day and Rene Malingre for their reviews of recent studies on laboratory animals who became dependent on the lenses they were given, and who developed myopia in an impoverished visual environment.

We are told to interpret these studies "with caution" although I'm not sure what is meant by "caution".

What I think the cautious thing for lens manufacturers to do at this point would be to put warning labels on distance glasses along the lines of "Use of these lenses may be hazardous to your eyesight. Distance lenses have been proven to increase myopia in laboratory animals." A similar warning could be devised for tinted lenses, which create an impoverished visual environment.

Also, cautious optometrists should make their patients -- especially the young ones -- aware of these laboratory studies. This could help them if one of their patients ever decides to sue for not warning of the possible side-effects of the treatment -- standard practice in all other areas of medicine.

It seems to me that the laboratory studies were designed specifically to be inconclusive. In spite of this, and in spite of the ho-hum reaction by optometrists to the studies, the studies are entirely consistent with the hypothesis that refractive error in otherwise healthy eyes is 100% controllable by manipulating visual stimulus.

I believe it is only a matter of time before a conclusive study is run, proving that glasses reinforce the defect that they compensate for, and those who treat refractive errors with compensating lenses will be forced to change their ways or go out of business.

[...]

> I do not consider the prescription of spectacles for myopia treatment.
> They are simply a visual aid. They certainly do not "treat" myopia,
> they simply enable the wearer to see distant objects clearly.

Hooray for you! Unfortunately, many docs I've corresponded with seem unable to tell the difference. Many of them call distance lenses for

myopia "standard treatment" and attach no consequence to the fact that someone's acuity is only their "corrected" acuity. Many times when I say that conventional eye science offers no treatment for myopia, doctors say, "whaddaya mean, we prescribe lenses!" When I say there should be studies that examine the difference between the advance in myopia among those with and without glasses, they say "what? And deny children treatment?"

> There
> is no evidence they make matters worse, either, in humans.

There is plenty of evidence. Every child who wears glasses for myopia gets worse. More than once, I've heard of a kid who wears glasses and whose brother or sister -- with the same degree of myopia -- refused. The eyesight of the sibling who chose to wear glasses got much worse. In addition, there are books by retired (of course) optometrists (Joseph Kennebeck, Jacob Raphaelson) who, against their professional training, and after years of prescribing distance lenses for myopia, came upon ways to treat myopia successfully. I will reprint from them at a future date. Needless to say, their reports are not to be found in any of the mainstream journals.

First of all, I love credit cards. Secondly, who's living in an ivory tower here? Would you be able to count on funding from Bausche and Lomb etc. if you planned a study that might prove that their product was harmful? Would you be able to remain on friendly terms with your optometric society buddies if you came out and said, "you guys are crippling children with your so-called treatment!" It's not a conspiracy, it's just the politics of the game of science. I've talked with an author of an article on myopia training who said he had to tone down his claims before they would publish his successful experiment results; he also had trouble getting the optometrists and even the military (who want to remain selective) to cooperate in setting up the experiment -- he had to compromise his experimental design. And this report was published in a behavioral optometry journal! Even behavioral optometrists are under enormous pressure not to rock the boat, since they depend on referrals from ophthalmologists.

> I would hazard a guess that most optometrists haven't made themselves

> >controllable by manipulating visual stimulus.
>
> Another Alex sweeping generalisation. The results aren't as clear
> cut as you would obviously like to believe.

You're right. The studies don't imply with certainty that my position is correct, but then again, that's not what I said. I said they are CONSISTENT WITH and are thus EVIDENCE FOR my position.

See the following article

> for evidence for inherited characteristics, for example:

>

> Zadnik K, Satariano WA, Mutti DO, Sholtz RI, Adams AJ. The effect of
> parental history of myopia on children's eye size. Journal of the American
> Medical Association 1994;271(17):1323.

There is no question that myopia runs in families. The question is, is myopia more genetic or more, as they say in anthropology "culturally transmitted". Body tension, like all mannerisms, is easy for children to pick up. Myopes tend to be tense people. According to many theories of myopia, myopia is (or results from) ocular tension of a certain type.

> However, the results of the studies are fascinating. I am sure they will
> have application to humans. However, just because something works
> in one animal doesn't mean it will work in another.

True enough. But obviously these experiments were meant to say something about HUMANS. What I find especially relevant is the implications of prescribing distance lenses for preschoolers.

>

> Alex, think a little kinder towards your fellow human. There are no
> world-wide conspiracies in physiological optics. Science doesn't work
> that way.

Rene, think a little kinder towards your colleagues in vision science. They are not accusing anyone of conspiring. They're more concerned with building a coherent theory of vision development than staging a witch-hunt.

Whoa, there! I don't share your linguistics training! I don't quite understand what you mean. I thought I said that you thought that there was a conspiracy in vision research. I cannot read your initial statement any other way. I didn't say that you were conspiring.

In optometry, the word "acuity" means "corrected acuity." It is a measure of the best vision that that eye can obtain. "Vision" means uncorrected vision. "Vision with glasses" means vision through a persons spectacles. In an emmetrope, acuity = vision. For an uncorrected myope, vision <> acuity. For an undercorrected myope, vision with glasses <> acuity. Thus, "acuity" has a specific meaning.

>Many times when I say
>that conventional eye science offers no treatment for myopia, doctors

Yes, well, what is the linguistics term? Semantics? Different people attach different meanings to the same word. They mean, "What? Deny children the ability to see things further away than their nose?"

"Every child who wears glasses for myopia gets worse." Think about that one for a while. The kid wasn't always myopic. The axial length grew to a point where the image of a distant object fell in front of the retina. The child then had blurry vision, and was functionally better off wearing glasses. The axial length continued to grow. The image plane kept moving. Of course the myopia increased. You're implying that the myopia was made worse by the glasses. Don't you think the same process that caused the myopia in the first place would continue anyway? As I said, glasses are not a treatment!

>

Me too. That was just a gentle jibe, attempting to say that your little conspiracy theory was as ridiculous as some others.

Secondly, who's living in an ivory
>tower here? Would you be able to count on funding from Bausche and Lomb
>etc. if you planned a study that might prove that their product was
>harmful?

No! However, I could probably count on funding from the National Health and Medical Research Council!

Would you be able to remain on friendly terms with your >optometric society buddies if you came out and said, in effect, "you guys >are crippling children with your so-called treatment!"

Yes, if I had proof! Conventional optometry in Australia tolerates even the most controversial behavioural optometrists. In fact, a recent national president of the AOA is a prominent behavioural optometrist. We might snicker behind their backs about some of their theories, but we stand united as a profession.

It's not a >conspiracy, it's just the politics of the game of science. I've talked >with an author of an article on myopia training who said he had to tone >down his claims before they would publish his successful experiment >results; he also had trouble getting the optometrists and even the >military (who want to remain selective) to cooperate in setting up the >experiment -- he had to compromise his experimental design.

What, improve it? Have control studies? Have random selection of subjects? Use double-blind or other shielding procedures? Have objective rather than subjective measures? Fancy that!

And this >report was published in a behavioral optometry journal! Even behavioral >optometrists are under enormous pressure not to rock the boat, since they >depend on referrals from ophthalmologists.

Even behavioural optometrists are forced to back their claims with statistically significant evidence from sound experiments that are adequate to test their hypothesis.

Subject: Do negative lenses make vision worse?
Status: RO
X-Status:

Alex has suggested that I submit the following to I_SEE for the

benefit of those who don't access the sci.med.vision forum. It was submitted on May 31.

A thread has been appearing off and on for the past several weeks on the general theme of "Do contact lenses make myopia worse?" and "The dangers of distance lenses". In general, the answers have been an emphatic NO:

"Contacts DO NOT make the eye dependent on them or worse" --
Richard Allen

"Wearing...minus lenses to optically correct myopia will not make your vision worse..." --John Warren

"Write on, proclaim yourself knowing more than all the good scientists who have come before you, more than all the practitioners of the art you have studied these many weeks. Write on, guess at topics in our field, confuse well intentioned bright folks. Knock yourself out. The professionals who have a real commitment to people, will be around to pick up the pieces." --David Granet

O.K. O.K. We can take a hint. Us dumb lay persons should just keep quiet and uncritically accept any and all pronouncements by the experts. The problem is that many of the "facts" of ophthalmology are merely opinion masquerading as fact (opposing evidence is usually just "swept under the rug"). Paul Harris is right (see below). Much of the practice of medicine is based simply on opinion, never having been subjected to rigorous investigation. The negative-lens question is a good example.

My contention is that negative lenses DO MAKE VISION WORSE. Not only that, but the evidence is so strong for this that IMHO the burden of proof is on the doubters.

So, HOW do negative lenses make vision worse? Simple. They force the lens to accommodate more than they would without lenses, or with weaker lenses. (In speaking of contacts, I'm referring to the negative aspect of the prescription; the question of the possible effects from the fact of their being in direct contact with the eyeball is another subject).

When an uncorrected myope looks at infinity, the image he sees is blurred, the source of the blur being the focal point situated in front of the retina. However, the accommodative mechanism can do nothing to correct this because it is already at the limit of its effective action, i.e. it is relaxed.

When a myope wearing the full correction looks at infinity (for practical purposes, any distance 20 feet or greater), he sees clearly and there is no need to accommodate. But, any time that he looks closer than 20 feet, the focal point of the rays entering the eye moves backwards, to a point virtually behind the retina, producing a blurred image. In order to clear up the blur, his crystalline lens will need to adjust for this closer distance by refocussing so as to move the focal point forward toward the retina, and of course this is accomplished by contraction of the ciliary muscle.

What this boils down to is that the crystalline lens of the fully corrected myope accommodates more (in the sense of more often) than that of the uncorrected myope. Those who believe that wearing negative lenses has no harmful effects on vision are also saying, in

effect, that frequent and/or long-term accommodation has no effect on vision, in other words, on the refractive power of the lens. This is demonstrably NOT true.

I'm just guessing here, but I suspect that most eyecare professionals believe that the power of the lens in the resting state is a fixed value. On the contrary, the resting state of the lens depends on what the lens was doing previously.

A study of accommodative hysteresis (1) shows a very marked effect on the resting level of accommodation, i.e. the power of the lens at rest. Hysteresis (from the Greek, "to lag") refers, in accommodation, to the delayed effect of a particular fixation of the lens. The experiment shows conclusively that even a relatively short period of accommodation has a subsequent effect on the resting level of accommodation.

The subjects of the experiment, with acuities of 20/15 to 20/25, fixed their eyes for a period of 8 minutes on a target placed at their near point (the closest point at which they could maintain clear vision). Subsequently, their acuity was tested 8 minutes later and 16 minutes later. The results showed a significant increase in their lens power, i.e. their resting level of accommodation had increased, by 0.3 negative diopters.

The same test was performed with the target placed at the subjects' far point. In this case, the resting level of accommodation at 8 and 16 minutes after the test showed a decrease in lens power, although this was very slight.

In regard to the "decay period" (the extent to which the lens returns to its original state), it is especially significant that there was a marked difference in the behavior of the lens after looking at the near point compared to looking at the far point.

After 16 minutes, the near-point increment only diminished to 88% of its initial value, whereas the far-point shift had dropped to 33% of its initial value. Assuming an exponential decay function that asymptotes in five time constants, the far-point effect would dissipate in 72 minutes, whereas the near-point effect would require 10.26 HOURS.

The accommodative mechanism is preeminently a system whose purpose is to adapt the eye to whatever viewing conditions are present, so, it is just doing its job. When negative lenses produce more blur at near distances, the lens accommodates accordingly.

Someone suggested some time ago that the forum periodically post a "quackery warning" to alert the unwary to postings about unscientific, unfounded, new-age type advice on vision (Batesian theories, etc.).

What would be even more useful is a warning to the effect that some of the pronouncements about vision by the MDs and ODs on the forum should be taken with a great deal of skepticism. This is more insidious because some people are more likely to be overly impressed by an MD or OD after a name.

This demonstration of the long-term effect of maintained accommodation is not at all new. (At the risk of boring some sci.med.visioners, I am repeating excerpts from some of my posts of Dec.-Feb.) Many years ago Lancaster (2) reported on this phenomenon:

He states that "...if the accommodation is maintained a few minutes at the maximum, the near point does get nearer and the eye may become accommodated 20% to 30% or more, nearer than at the first. If the near point at the start was 6 D. it may become 7, 8, or 9 D. This...is due to the viscosity of the lens substance. An immediate rapid (about one second) change takes place when the lens adjusts itself for a near object, but if a maximum effort of accommodation continues to be made, the lens slowly (5 to 10 minutes) goes on changing its shape and becoming more strongly refractive.

"Commonly, when the eye, after such an intense effort of accommodation, is shifted to a distant object, although the ciliary muscle may promptly relax, it takes time (a few seconds to a few minutes depending on how long the near effort was continued) for the lens to regain its normal shape adapted to a distance. This is due to the viscosity which makes a change in the shape slow."

Other investigators have also demonstrated the slowness of lens changes in experiments on lenses removed from the eye. According to Kikkawa and Sato (3) "Application of an external force to the lens caused a rapid deformation followed by a second phase of slow deformation. On removal of the force, a rapid partial reversal of the deformation occurred and was followed by a gradual restoration; complete recovery was not achieved."

Kabe (4) reported a similar result from his investigations. He showed that when accommodation is increasing, the change in the apparent curvature of the anterior surface of the lens is slow and continuous, but when accommodation is decreasing, there is a prompt, followed by a slow phase.

The slow recovery rate of the lens was shown dramatically in my own experiment in artificially-induced myopia (which produced an increase of 5 diopters). When the experiment was terminated (removal of the factors that had caused the 5 D. increase), the process began to reverse.

The significant point is the amount of time it took for the lens to return to its original refraction: several YEARS. This is not surprising, considering that my experiment involved several weeks of a situation which was, in effect, the equivalent of near-point fixation. Compare this with Ebenholtz's experiment, in which only 8 minutes of near-point fixation required 10.26 hours to reverse.

Ebenholtz drew the obvious conclusion by stating that "...the extraordinarily long decay time constants associated with near-point fixation suggest a potentially important role in the etiology of axial myopia." And "Since accommodative hysteresis implies a long lasting increase in ciliary muscle tonus, it is conceivable that the propensity toward hysteresis effects is related to the incidence of near-work induced myopia."

Logically, those who believe that excessive accommodation has nothing to do with myopia also believe that nearwork (usually in the form of reading) has nothing to do with myopia. If this post weren't already so long, I could list many dozens of studies that do show a relationship: submarine crews compared to National Guardsmen (significantly more myopia), Eskimo school-children compared with their parents who didn't go to school (far more myopia), university students compared with the general population, many studies by the Japanese. There are also studies that don't support the relationship, but so what? Which negates which? Although I haven't read all of

them, those that support the nearwork/myopia relation appear to be stronger and to outnumber those that don't.

In the face of all the evidence, it seems that only ophthalmologists and optometrists are stubborn enough to insist that negative lenses have no effect on vision and that nearwork has little or nothing to do with myopia.

Paul Harris, O D., in a recent post, quotes a study from the New England Journal of Medicine to the effect that "at least 85% of that which physicians do has NO BASIS whatsoever in having ever been studied at all. They just do it and it is the standard practice of care." This sounds like what the eyecare professionals do regarding full correction--they just do it, thereby perpetuating the same error year after year.

I'm not suggesting that they tell myopes to stop using their lenses (when I'm driving I don't want some uncorrected 20/400 myope coming in my direction!). But the least they could do would be to advise low-grade myopes to read without their correction if they are able to do so comfortably (the same if they use a computer or with other nearwork tasks).

This could very well produce a significant slowing in the progression of their myopia. Of course patients might return less often to change their Rx, ergo fewer lens sales. But, here's the good news (for the providers!)--simply tell patients that they need to buy TWO pairs of glasses, one with a slightly reduced Rx for general use and one with the full correction for more critical tasks such as driving, etc.

I don't think I am dogmatic about this. Give me a good, logical, scientific explanation of why long-term accommodation (caused either by negative lenses or nearwork) DOES NOT cause long-term changes in refraction and I'll issue a retraction.

Have an eyes day.

Myopia is a reaction to the world being perceived as unsafe. If you would like to stir up a little discussion, my clinical research implicates difficulties with sexuality being connected to the myopia, more than 50 percent of the time. These are unresolved perceptions like the reprimand. The sexuality component is more true in the presence of astigmatism associated with myopia Even in cases where my patients are having consistent 20/20 flashes, without glasses, I need to coach them on their ever present myopic behaviour of inwardness and not seeing the forest from the trees. Design I can do. Implement is another thing. For that I would need the help of an OD or Ophthalmologist.

All you'd have to do is each time there comes to your office a 9 to 14-year-old with a 1.0 diopters of myopia, and 20/40 vision, but who is doing fine in school, and who does not think they need glasses, and whose parents do not care one way or another whether the child gets glasses, flip a coin and do one of two things:

1) Tell them that their vision is poor now, but that if they are to get glasses at such a young age, there is a possibility that their vision will get worse than it would without the glasses. Tell them that this puts them at higher risk for retinal detachment. Tell them to sit closer to the chalkboard if it's hard to read, and use a pair of +1.00 D reading glasses for all close work, especially late night studying and written tests during school. Give them an eye chart so that they can monitor their own vision. Tell them to spend more time outside, and less time watching TV or playing video games. See them in a year.

2) Tell them that they need glasses. Tell them that by wearing the glasses they will be keeping their eyes healthy, and tell them to wear the glasses as much as possible, including when reading. Tell them that if they feel any discomfort, this is only a sign of adjustment and their vision is not getting worse. Tell them that they may think their vision is getting worse, but this is just an illusion. See them in a year.

Since such children are below the driving age, and their vision is 20/40, you cannot argue that they need glasses for driving. Since they are doing well in school, you cannot argue that they need glasses to read the chalkboard. Since such children do not particularly want to or feel the need to wear glasses, they will not consider themselves "guinea pigs". I know quite a few people who as children would have been more than willing to have had "accepted treatment[sic]" withheld from them -- that is, go for a year continuing to not wear glasses -- if they had been presented with the arguments for and against glasses. Probably far more than would ever willingly wear bifocals. And bifocal experiments are legion.

You are thinking of the Baltimore Myopia Project. First of all, it did not test the Bates method, but some unspecified exercises designed by optometrists. Significantly, the participants continued to wear their regular prescription glasses throughout the experiment. Second of all, it was a pilot study; it only lasted a few months. Thirdly, not all eye doctors who reviewed the study believed it produced negative results. Some said that the results, while modest, were significant.

There was an article written in the Journal of Behavioral Optometry 1992 (vol. 2, no. 2, p. 47), called "The Baltimore Myopia Study: 40 Years Later." Here is the abstract:

:The Baltimore Myopia Project (BMP) is one of the most frequently cited
:studies concerning the efficacy of vision training. As a result of the
:study two sets of publications appeared in the literature between 1946
:and 1947. One set was written by an ophthalmologist and the second set by
:optometrists. The ophthalmological articles stated that the results of
:the study showed that vision training was not efficacious in the
:treatment of myopia. The optometric articles reported results supporting
:efficacy of vision training in the treatment of myopia. After reviewing
:each of the articles in detail, the apparent contradiction became
:understandable: the two sets of articles did not utilize the same sets of
:data. We performed a post hoc analysis of the available data using modern
:statistical methods. Our conclusions are that there were statistically
:significant positive changes in visual acuity and that the
:ophthalmological opinion that the BMP indicates a lack of support for the
:efficacy of myopia reduction vision training is unfounded.

Subject: Re: Eye Pressure and Myopia

Alex,

The chick corneal response was greater distortion of the corneal shape with less intraocular pressure.

The older medical /optometric instrument was a Schiottz tonometer. It actually measured some of the corneal rigidity. The new puff and Goldmann tonometers minimise the rigidity component.

I find the less rigid the cornea the more myopia progression occurs. The animal studies here show that the eye changes rigidity with myopia progression. A softer sclera is found in the myopia group.

Jim

Via: Ethernet hch2@cornell.edu

Dear Sir :

About your ongoing research on the development of the eye.

It was with a great deal of interest that I read an article in Discover magazine in the October 1995 Issue concerning your ongoing work on the development of the eye and its relation to bio feedback.

I come from a family of 7 where both the parents are with normal vision and where all 5 of the children were nearsighted and read a lot. I graduated from Queen's University in 1977 with a first class degree in Civil engineering and also graduated with courses in Genetics. This interestingly enough, gave me a background in evolution, genetics, mechanics and physics.

I had believed since I was about 15 that there was a causal link between eye development and Myopia and indeed was immensely interested when I read an article supporting that position.

At first (around 1972) I had hopes that by carefully managing the use of my eyes I would be able to reverse the myopia about (- 1 dioptre). This I theorized would be done by using reading glasses to simulate an at rest condition. I experimented with various lenses used while reading and studying ranging from +1.5 dioptre to + 2.5 dioptre, all the while thinking of and studying the structure of the eye to see if I could gain a better understanding of the process.

Although my eyes never improved they did not get any worse from a refractory point of view. It was relatively easy to experiment since my eyes did not have any astigmatism. I could therefore purchase glasses at the drug store for reading . I also talked my eye doctor into prescribing glasses at -.75 dioptre that I would wear while attending classes. This did not do anything even though I played around with this concept for years. One thing that it did do was make me more aware of the minor changes which seemed to occur with my eyes due to atmospheric pressure, influence of alcohol and marijuana use, reading, driving, smoking.

After I graduated 1977, I married in 1978 and had a family. My wife was a graduate nurse at University of Toronto and was mildly myopic with -.50 in the right eye and -.75 in the left eye. She did not wear her glasses which probably helped to prevent her vision from changing further.

We have two daughters aged 15 and 11 both of whom have eyes that are almost perfect as far as spherical corrections are concerned they are both at 0 dioptre +/- .25. From the time that they were young I have encouraged good eye habits in both of them, ie don't sit too close to the TV , Head up when they walk Etc. When we moved to Timmins in 1987 we went to see an eye doctor by the name of Al MacIvor. He was talked into prescribing reading glasses for both of the kids . My reasoning was that since my eyes had stabilized at about -1.00 to -1.25 dioptre that reading glasses of +1.25 dioptre would probably be about the right level for them.

A l said that both of the girls had very little reserve in their eyes and would both be myopic by the time they were 15. He looked at me with a bit of a glazed look in his eyes when I started talking to him about my ideas and probably thought I was talking about pyramid glasses etc. I insisted that the prescription not contain any cylindrical corrections.

This now 1995 and the girls are fine. Their eyes basically have not changed in 8 years. They both are avid readers and computer users and they both wear their reading glasses.

In a further elaboration to the above I have noticed that in the workplace where I work there is a very high incidence of occupational myopia in office workers. Truck drivers never develop myopia . Similar to your observations about the pilots who have good vision prior to their studies and poor vision after.

I am not looking for anything from this. Just trying to help where I can and enjoying the chance to finally be able to transmit my information to someone who takes it seriously and has the professional credentials and interest in pursuing it further .

I attach a brief synopsis of my ideas to you:

A THEORY ABOUT EYE DEVELOPMENT

When a child is born his eyes are not fully developed. In a complex interaction between the ocular structures the child inherited and the environment the eyes develop over time.

At this point we may well ask ourselves why nature would not see fit to endow a child with a perfect eye . Would it not be easier to create a perfect eye and not one that requires and goes through all kinds of changes in refractive powers as it develops. The answer is not at all obvious but may be deduced using plain common sense combined with a bit of basic knowledge about biology, genetics and engineering. It is not clear that in an evolutionary sense it is important to have good vision either.

According to biological laws a child inherits all of his physical traits from his parents. In the case of the eye these traits could be for instance lens power, eyeball size, elasticity and tendencies towards certain patterns of eye development which we will get into later. One can see that for instance the inherited/genetic coupling of a small eye with a large eye (a genetic simplification) could lead to problems in the sense that a lens adapted to a small eye would focus improperly when placed in a large eye.

However nature in her wisdom has evolved an eye that usually develops

normally unless of course the usual pattern of development is interfered with as we shall see later.

The easiest way for this mechanism to work would be to have the eye interact with the environment into which it sees. By a simple bio-feed back mechanism(which by the way does not always work perfectly) the eye strives to adjust its accommodative/resolving/brain matching powers to develop a normal seeing ability.

In order to act properly this feedback system has to act slowly in order not to overreact to short-term situations. It acts in such a fashion as to create a normal eye not in our modern environment but in an environment as it existed years ago before the advent of modern television, newspapers, and the avalanche of printed materials which are before us to-day. The importance of good vision was a powerful evolutionary force in the days before corrective measures were common or even invented. Such a powerful force would have evolved systems which in some cases are not that beneficial in the different modern visual environment. And yet it is true that in many situations then as well as now it is a handicap in the Darwinian sense to be endowed with good vision.

The biofeedback system would act more rapidly at birth and gradually slows down in later years. In fact if this feedback developmental system is so important to the proper development of the eye that should the eye not interact properly with its environment before the age of six adequate development may never occur. This is the predominant reason why eye specialists recommend patching the strong eye in cases of lazy eye- to force the lazy eye to interact with its environment.

How does this interaction with the environment take place ? The answer relates to many things - nerves , receptors at the back of the eye, eye drainage/ elasticity/accommodative powers/size etc. We are concentrating this discussion on the aspect of development which relates to physical eye development in terms of focusing ability and size. Research needs to be done in order to quantitatively pin down all of the relevant parameters.

One of the first thing the brain trains the eye to do after birth is to focus on things such that a clear image is developed by a proper focus on the retina. Basically when the eye sees something it tries to focus on it. If the object is out of range of the eyes focusing/acuity ability makes the person see only a blur as the brain can only make limited sense out of the nervous impulses sent back to the brain. In the normal eye the focusing muscles which act on the lens are at rest when the eye is focused on objects at infinity. Any objects which are looked at any closer than 20' involve the use of these focusing muscles and objects which are very close to the eye involve a greater use of these muscles.

The physical act of focusing causes a change in the eye's internal drainage system. This is the system which balances incoming fluid with outgoing fluid. The greater the strain on the focusing muscles of the eye the greater the constriction on the canals of Schlemm which are located at the juncture of the iris and cornea. It is not clear if the constriction amount is related to the degree of focus required or in genral terms to the use or non use of the focusing muscles. It may take quite a period of time for pressure to build up or decrease. As the pressure builds up in an eye the natural elasticity of the eye allows the eye to stretch and actually expand like a balloon but on a small scale. Over time and with this constant interaction between internal eye pressure and elasticity of the eye the eye may/will undergo a permanent minute change in size and shape which is enough to alter the refraction distance from the retina to the lens.

The eye can be compared to a kitchen sink : There is a faucet to allow water to run in and a drain to let the water run out. Unlike a sink there

is no overflow and excessive pressures in the eye can build up.

These effects are very gradual and are usually overlooked. In adults the effects are minimal because the eye loses its elasticity as we get older and because the demands of adult life may require a different useage pattern. In a young child the changes can be most pronounced. Some children are born with one normal eye and one eye in which the drainage system is blocked. In the abnormal eye extreme nearsightedness and blindness eventually result combined with an abnormal increase in eye size.

Nature has created this system of natural feedback to allow the eye to develop normally in response to an environment. After children are born , over time their eyes develop normal vision. The responses to the natural feedback are slow in occurring and each person's response would vary minutely from everyone else's. In a normal eye, at rest the light rays would be focused perfectly at the retina when the light rays are coming in from a distance of over 20 feet. The important thing to note is that it does occur and the effects can best be understood by examining the two extreme scenarios which might develop. These scenarios would of course be important in the case of Spherical aberrations only. When a person starts to look at astigmatism and all of the complications that might occur from such a consideration the situation becomes much more complex.

Scenario #1: A person's eye is always gazing off into the distance. Nature's feedback system will work towards the eye muscles being completely relaxed when the eye is looking off in the distance. In order to see close the eye will have to actively focus.

Scenario # 2 A person's eye is always looking at a book 14 inches away . Nature's feedback system will work towards the eye muscles being completely relaxed when the eye is looking at a book 14 inches away. This will occur through actual structural changes of the eye. When the person involved tries to look farther away things will seem blurry. In young children some of these effects are temporary but as the children get older the effects become more and more permanent. Once the effects become more permanent the eyes will have to wear corrective lenses for myopia since the muscles would already be completely relaxed.

A complete understanding of the biofeedback system as it applies to the focusing power of the eye and its variations among individual's would allow trained individuals to interfere with the process and steer the eye's development so that the focusing muscles are at rest when the eye is looking at something far away. The biofeedback system is most active in the young and has a minimal effect after the early twenties.

It is not meant as a criticism but the present state of the art in eye care does not recognize this biofeedback mechanism and in instances creates a spiralling biofeedback effect leading to extremes in eye development. Nature's biofeedback system does not respond to corrective lenses it responds to the accommodative responses required to focus.

Suppose a child likes to play Nintendo and holds his face away from the screen about two feet away. Say that child's eye has responded to this environment and developed a need for a corrective lenses of -1.00 Dioptres. The eye doctor comes along and prescribes a lens of -1.00 Dioptres. The child may goes back to this environment. . If the child plays nintendo but does not wear his glasses then no further harm may result. If the child however wears his glasses to play nintendo then Lo and behold the first thing you know the child's eye develops a need for another - 1 Dioptres in addition to his initial 1 Dioptres lenses and so the cycle continues. This cycle is slow and eventually may stop once the child gets a little older. Sometimes to halt this process doctors (without any real concept of the

underlying mechanism)prescribe bifocal lenses to ensure that when the eye is engaged in close activities the eye is at rest. This may apply particularly when the child does a lot of reading. This bypasses the biofeedback system and slows or prevents further adverse changes.

Nature has evolved unorthodox ways ways to prevent the biofeedback system from running amuck in young children. Some of these are as follows: Short attention span, eyes get tired quickly, minor astigmatism, dyslexia or inability to read. All of these prevent children from becoming completely absorbed in activities which involve considerable focusing on close objects. The most dangerous activities for children are computer terminals, books, and watching TV from a close distance. These activities all have several things in common: They involve a good deal of strong focusing over extended periods of time and they are all relatively new activities in the evolutionary time scale. In other words eye development has evolved in response to a different set of environmental parameters.

It would seem entirely reasonable that proper eye care should recognize nature's Biofeedback system and act accordingly to ensure proper eye development.

Articles have been written to indicate that there is strong correlation between Intelligence and nearsightedness. It would be interesting to see what correlation there is between eye habits and nearsightedness taking into account the imposed environmental stresses. It is noted of course that persons with High IQ may have very different eye habits than people with low IQ. In fact the very environments themselves that contribute to high IQ may also contribute to nearsightedness.

Such a study would filter out such important factors as:

- 1)Description of activity.
- 2) The intensity and duration of the activity.
- 3) The level of refractive accommodation required by the eye to focus on the surface.
- 4) The type of rest period and the duration of the rest periods for the eyes.
- 5) The time of day various activities are engaged in and what releases might occur.
- 6) Initial state of the eye.
- 7) Age.
- 8) The distance from the eye to the surface being focused on.

Example # 1 Reading:

Scenario #1:

- 1)Description of activity.

Reading

- 2) The intensity and duration of the activity. 1/2 hour at a time
- 3) The level of accommodation required +1.25 Dioptres
- 4) The type of rest period and the duration. 10 hours of sleep
- 5) The time of day . before bed
- 6) Initial state of the eye. normal 0 Dioptres correction Left and right
- 7) Age. Ten years old
- 8) The distance from the eye to the surface. 14 inches.

Scenario #2:

- 1)Description of activity.

Reading

- 2) The intensity and duration of the activity. 1/2 hour at a time
- 3) The level of accommodation required 0 Dioptres no glasses
- 4) The type of rest period and the duration. 10 hours of sleep
- 5) The time of day . before bed
- 6) Initial state of the eye. nearsighted -1.25 Dioptres correction Left

and right

7) Age. Ten years old

8) The distance from the eye to the surface. 14 inches.

Note the difference in the two scenarios. In the first example the eye is normal. In the second example the eye is nearsighted but the child does not wear corrective lenses and so his eyes do not need to engage in any refractive corrections.

Example # 2 watching TV:

Scenario #1:

1)Description of activity.

Watching TV

2) The intensity and duration of the activity. 2 hours at a time

3) The level of accommodation required +.10 Dioptres

4) The type of rest period and the duration. 10 hours of sleep

5) The time of day . before bed

6) Initial state of the eye. normal 0 Dioptres correction Left and right

7) Age. Ten years old

8) The distance from the eye to the surface. 16 feet.

Scenario #2:

1)Description of activity.

Watching TV

2) The intensity and duration of the activity. 2 hours at a time

3) The level of accommodation required +1.00 Dioptres

4) The type of rest period and the duration. 10 hours of sleep

5) The time of day . before bed

6) Initial state of the eye. normal 0 Dioptres correction Left and right

7) Age. Ten years old

8) The distance from the eye to the surface. 3 feet.

Not the distinct difference in the refractive accommodation required between the two scenarios. In Scenario # 2 the child is more likely to develop nearsightedness than in scenario # 1.

Example # 3 walking :

Scenario #1:

1)Description of activity.

Walking- eyes looking in the distance

2) The intensity and duration of the activity. 1 hours at a time

3) The level of accommodation required +0 Dioptres

4) The type of rest period and the duration. no rest period required eye is at rest

5) The time of day . evening

6) Initial state of the eye. normal 0 Dioptres correction Left and right

7) Age. Ten years old

8) The distance from the eye to the surface. 20+

Scenario #2:

1)Description of activity.

Walking- eyes looking at the ground

2) The intensity and duration of the activity. 1 hours at a time

3) The level of accommodation required +.75 Dioptres

4) The type of rest period and the duration. brief rest periods upwards glances

5) The time of day . evening

6) Initial state of the eye. normal 0 Dioptres correction Left and right

7) Age. Ten years old

8) The distance from the eye to the surface. 4 to 5 feet

Not the distinct difference in the refractive accommodation required between the two scenarios. In Scenario # 2 the child is more likely to develop nearsightedness than in scenario # 1.

Exercise:

Many practitioners believe that a person should exercise their eyes periodically to reduce the incidence of eye deterioration and so on that develops. I have never seen a mechanism explained for why this exercise may be beneficial. The Elasticity, fluid balance ideas would suggest that so called exercise of the eye would be important since it would prevent the fluid balances in the eye from being out of balance for extended periods of time. So would an attention deficit disorder be beneficial in the young to prevent the eye focusing too long at close things and adversely triggering the biofeedback mechanisms.

Your patience in reading the above is appreciated. Should you wish to confirm receipt of this letter I would appreciate it .

Sincerely Yours

My mother (she's in her mid 40's, too) is keeping her eyes from getting worse by palming, shifting, and just physical exercise for the eyes (rotate them, look up-down-right-left, etc.). She was in bad shape last year and started wearing glasses; but now that she's doing those exercises, she doesn't need them anymore.

Yours,
Ari Solovyova

> Does anyone know if it is possible to cure amblyopia
> or lazy eye?

Yes, yes, yes, amblyopia can be cured, and contrary to popular belief:

- 1) you don't have to wear a patch all day,
- 2) there are lots of things you can do to improve vision in the "lazy" eye on top of the patching,
- 3) there is no age limit for improvement!

One of the most important aspects of amblyopia is training the eye to USE THE FOVEA, or central part of the eye, for detail viewing. This is called "central fixation" Many persons with amblyopia -- for whatever reason -- repress foveal vision. That is, they use a less sensitive part of the retina in order to see things. This is called "eccentric fixation". Just wearing a patch won't necessarily get you to use the most efficient part of your retina, and just forcing yourself to "try to see" while still engaged in the old habit of seeing with the wrong part of the eye, will only cause eyestrain.

Your best bet is to see a licensed eyecare practitioner who can help you "find your fovea", and who can prescribe various activities to get you to use it correctly. To find one (the practitioner, not the fovea!) in your area, please see under "finding help" at

http://silver.ucs.indiana.edu/~aeulenbe/i_see.html

In addition, William Bates's book "Better Eyesight Without Glasses" gives lots of tips on how to acquire central fixation. In fact, the book was originally published by the author's so-called "Central Fixation Publishing" company. According to Bates, lack of central fixation underlies all vision problems, and achieving central fixation will cure all errors of refraction (i.e. eliminate the need for glasses). Bates evidently had stricter standards for "central fixation" than what is used today, since most modern practitioners do not find eccentric fixation in the majority of people whom they feel need glasses, and they also find many amblyopes with what they define as central fixation. But in any case, if central fixation is what you need, the Bates system of perceptual and memory training is one tool with which you can acquire it.

Subject: optometric amblyopia treatment
Status: RO
X-Status:

Optometrist Merrill Allen, Professor Emeritus at Indiana University, has developed a flash-therapy treatment with a device known as the "Translid Binocular Interactor". It is used by many optometrists across the US for

the cure of amblyopia and strabismus. Dr. Allen writes in one article (in /Frontiers in Visual Science/, Springer-Verlag, 1977), referring to its use in treating amblyopia...

:The success rate of [patching the better eye] is only about 50% with the younger patients being more responsive. In fact, an often repeated clinical statement is that anyone older than eight years cannot be treated if they have amblyopia. Another clinic "rule" is that corrected acuities poorer than 20/200 are probably organic, and, therefore, cannot be treated.

:Fortunately, treatments that are more aggressive than the occluder [patch] are available, and the eight year rule and the 20/200 rule appear to be myths. For example, Fig. 1 [curve decreasing logarithmically from 20/2600 at 0 hours to 20/250 at 57 hours] shows the recovery curve for a nine-year-old female having an initial corrected acuity of 20/2600 who was treated with flash therapy applied in the macular region of the amblyopic eye. Similar recoveries have been observed for patients in their 30s and with acuity of light perception only. Older patients have not been available for treatment. My oldest patient for the successful treatment of lifetime strabismus was 58 years of age.

:The shape of this visual acuity recovery curve seems to be typical based on clinical experience and may be used for prediction purposes. All patients do not respond at the same rate, either due to treatment differences, to depth of the anomaly or to age, but the curve shape seems to be similar for all. Thus if it took 45 hours to attain 20/200, 20/100 will take approximately 90 hours, 20/50 approximately 180 hours and 20/25 approximately 360 hours of treatment. At the rate of one hour per day, 20/25 would thus be expected in one year starting at 20/2600 in this nine year old's case, assuming the same intensity of therapy continued throughout.

Here's an abstract of an article appearing in the official journal of the American Academy of Optometry:

* * *

"Anisometropic amblyopia: is the patient ever too old to treat?"

By Bruce Wick, Michael Wingard, Susan Cotter, and Mitchell Scheiman
/Optometry and Vision Science/, vol 69, no. 11 (Nov 1992), pp. 866-78

ABSTRACT:

:Amblyopia is an example of abnormal visual development that is clinically defined as a reduction of best corrected Snellen acuity to less than 6/9 (20/30) in one eye or a two-line difference between the two eyes, with no visible signs of eye disease. We describe a sequential management program for anisometropic amblyopia that consists of four steps: (1) the full refractive correction, (2) added lenses or prism when needed to improve alignment of the visual axes, (3) 2 to 5 h/day of direct occlusion, and (4) active vision therapy to develop monocular acuity and improve binocular visual function. We examined records of 19 patients over 6 years of age who had been treated using this sequential management philosophy. After 15.2 (+/- 7.7) weeks of treatment the Amblyopia Success Index (ASI) documented an average improvement in visual acuity of 92.1% +/- 8.1 with a range from a low of 75% by a 49-year-old patient to a maximum of 100% achieved by 42.1% of the patients (8 of 19). Patients who had completed therapy 1 or more years ago (N = 4) maintained their acuity improvement. From these results we conclude that following a sequential management plan for treatment of anisometropic amblyopia can yield substantial

:long-lasting improvement in visual acuity and binocular function for
:patients of any age.

Bruce Wick and Michael Wingard may be reached at the College of
Optometry, University of Houston.... (713) 743-2053
Susan Cotter's number in Olympia Fields, Illinois is (312) 481 5600
Mitchell Scheiman's number in Philadelphia is (215) 276 6057

* * *

Another outspoken researcher in the field of amblyopia therapy is

Arnie Sherman, OD, of Merrick, New York (516) 868 2266

Dr. Sherman, taking an issue with one of the assumptions of the
abovementioned study, argues that full correction of refractive error in
amblyopia is counterproductive. Writes Dr. Sherman ("Alternative Treatment
for Anisometropic Amblyopic Patients: A Case Report", Journal of
Optometric Vision Development 1993, vol. 24, pp. 25-27):

:Correcting the full refractive error is often counterproductive and may
:cause the patient to readapt once more and create a larger refractive
:error in order to maintain functioning in every day tasks. This phenomenon
:typically occurs with hyperopic strabismic amblyopes who continue to
:increase in hyperopia even after the full Rx found under cycloplegia is
:worn for a short period of time.

The same view with regard to full correction is held by Dr. Allen. See
"How to Eliminate Hyperopia" on the I_SEE page.

Dr. Allen says 1 out of 5 "Vision Training" optometrists use it. I called
one optometrist in Ohio (Drusilla Grant) and she says she uses it.

> Has ANYONE studied it??? (besides Allen)

Definitely not, which irks Allen. Not even the typical "we tried your new
technique and it didn't work, so there" study. However, somebody did go
ahead early on and steal Allen's patent (which has now expired) and
marketed an identical device.

For what it's worth, the TBI is described (neutrally) in Schapero's 1971
amblyopia text, along with other inventions of Dr. Allen (such as the
sectorized rotating disk, which produces the same effect). Ciuffreda et
al's 1991 amblyopia textbook, however, does not mention the device at all,
or Allen.

>Biofeedback Vision Retraining has been used successfully with lazy eye.

>Peter Behel in the San Francisco Bay area was doing the work a while back.

I would imagine that biofeedback could be helpful, but to answer Jeffrey, yes patching the good eye forces the lazy eye toward better, more central fixation, since the root cause of amblyopia is that the brain has never really learned how to 'aim' the eye well.

You can easily see how this works if you direct your gaze to any edge of your computer monitor and realize that you can't read anything on the

screen except very large letters. Amblyopia is like not being able to aim the eye closer to the letters you want to read.

As to how long, patching works best in small children where I've seen dramatic improvements after a month or 2 of continuous patching. With older kids it takes longer and with adults it can really be tough mostly due to the inconvenience of walking around all day with the good eye patched.

The time is also related to the depth of the amblyopia. 20/400 takes a LOT longer than say 20/40.

Bill

The best advice I know of is to have a healthy diet, full of all the vitamins and minerals you need.

Brigitte Mars, in an anthology /American Herbalism/, writes: "The lenses of our eyes contain more Vitamin C than any other body part, except some endocrine glands. Vitamin C and E may both help prevent cataract formation by preventing oxidative damage. In cases of cataracts, vitamin C is usually deficient."

Anything that improves circulation -- the inflow of nutrients to the eye, and the outflow of toxins from the eye. Bilberry (aka Huckleberry) extract, rich in anthocyanosides, has been shown to improve circulation by strenghtening capillaries. Says Heinerman's /Encyclopedia of Healing Juices/: "The huckleberry juice compounds may also offer significant protection against the development of retinal (macular) degeneration and cataracts, particularly diabetic retinopathy and cataracts."

J.F. Balch, "Prescription for nutritional healing", p.173:

"This form of cataracts [i.e., in older people] is often caused by free radical damage. Exposure to ultraviolet rays and low-level radiation from x-rays leads to the formation of reactive chemical fragments in the eye. These free radicals attack the structural proteins, enzymes, and cell membranes of the lens.

NUTRIENTS

Copper, manganese, selenium and zinc (3 mg copper and 50 mg zinc daily) Important for proper healing and for retarding the growth of cataracts

L-Lysine (amino acid)

Important in collagen formation, which is necessary for lens repair. Also neutralizes viruses implicated in lens damage

Pantothenic acid (B5) 500 mg daily

An antistress vitamin

Thiamine (B1) and Riboflavin (B2) 50 mg each daily taken with the B complex
Important for intracellular eye metabolism. Riboflavin deficiency has been linked to cataracts.

Vitamin A 25000-50000 IU daily

Vital for normal visual function.

Vitamin C 3000 mg daily in divided doses

Free radical destroyer. Lowers intraocular pressure.

Vitamin E 400 IU daily

Free radical destroyer.

Also: avoid antihistamines. Bilberry contains bioflavonoids, the removal of chemicals from the retina of the eye."

You can consult Earl Mindell's "Vitamin Bible" for a list of food that contain those important nutrients. A bit of personal advice: large doses of Vitamin C should be taken as ascorbates, and not as ascorbic acid, to avoid stomach distress. I found calcium ascorbate powder with bioflavonoids in my health food store, which tastes nice, doesn't trouble my sensitive stomach, and seems to help. :-)

Good luck,

Ari

Subject: Re: cataracts

Status: RO

X-Status:

At present, accepted prevention methods for Cataracts are few.

1 Avoid trauma

2 Avoid Electric shock

3 Avoid use of steroids, (they also cause increased eye pressure, glaucoma)

4 Avoid UV radiation exposure, (wear a hat with a brim, sunglasses)

5 Avoid Infrared Radiation, (hobbies like blowing glass, metal work, heat lamps)

6 Take an Asprin Daily (this is also good for your cardiovascular system)

Since they upset my stomach, I take a chewable "Adult" baby asprin. Tylenol, Ibuprofen, or Aleve will not substitute.

7 Don't get diabetes

8 Don't get any inflammation of the eyes from any cause. (Sarcoid, Iritis, Uveitis) If you have any eye that is red and sensitive to light, see your eye doctor ASAP.

9 Don't worry be HAPPY: Cataracts can be easily removed with an accurate implant and no stitches are needed. Most of my patients only need reading glasses after cataracts.

10 Cataracts are a blessing: If you are +1 or -1 or greater, your implant lens will be more accurate than your prior natural lens for your optical needs: Your glasses will not be as strong, you will not be as dependent on eyewear. Why worry about RK, Laser, or VT if you will get cataract surgery to correct your myopia as a Bonus!

11 Several amino acids are used to prevent cataracts. None are accepted in

the US.

12 Anti-free radical vitamins are likewise recommended around the world, but the lack of evidence leaves me skeptical.

13 The truth is that as all of us live longer we will all increase our age related risk of cataracts.

What's the justification for this? What study proved heavy aspirin users get fewer cataracts?

> 8 Don't get any inflammation of the eyes from any cause. (Sarcoid, Iritis, Uveitis) If you have any eye that is red and sensitive to light, see your eye doctor ASAP.

What's the connection? By the way, I've read in several sources that SUNGLASSES INCREASE susceptibility to eye inflammations, and of course make you more light-sensitive.

> 10 Cataracts are a blessing: If you are +1 or -1 or greater, your implant lens will be more accurate than your prior natural lens for your optical needs: Your glasses will not be as strong, you will not be as dependent on eyewear. Come on, now, let's not forget the risks of cataract surgery, AND the increased risk of macular problems. Without the lens, you'll diminish your ability to accommodate.

> 11 Several amino acids are used to prevent cataracts. None are accepted in the US.

I guess it would deprive too many cataract patients the "blessing" of surgery.

> 12 Anti-free radical vitamins are likewise recommended around the world, but the lack of evidence leaves me skeptical.

Is there any more evidence for aspirin?

> 13 The truth is that as all of us live longer we will all increase our age
> related risk of cataracts.

The truth is that older people have had more chance to accumulate toxins in
the body and have poorer circulation.

On Sat, 16 Sep 1995, Sally Cooper wrote:

> I'm confused. We are told that natural sunlight is a good thing for
> eyes. "Sunning" is, I believe, part of the Bates method.

The latest version of the Bates method recommends "sunning" to be done
with the eyes closed. That is, let the sun shine directly on your
CLOSED eyelids as you move your head back and forth.

> Then we are told that we must wear sunglasses at all times to prevent
> cataracts.

I think various studies show that people who spend all their day outside
in the bright sunshine have a greater risk of getting cataracts. Robert
Roosen referred to one of these. In this study, the people were all
fishermen, who receive lots of sunlight reflected onto their eyes from
the water.

I do not believe there has been one study that shows that people in
typical urban environments who regularly wear sunglasses have a lower risk
of getting cataracts than those in the same environment who don't. I don't
even know if there has been a study that shows people who work in the sun
and wear sunglasses have less a chance of getting cataracts than those who
work in the sun and wear no sunglasses.

Common sense would say our eyes evolved to tolerate sunlight. However,
there's that "ozone depletion" factor, too. I don't know how significant
it really is. The development of cataracts does appear to be quickened by
a life in the sun, but there are other more important factors, such as
nutrition. For example, it could be that vitamins (anti-oxidants) can
repair damage done by light before that damage evolves into a cataract.
Also, the act of focusing near-far-near forces circulation of the eye
fluids. This has been thought to prevent cataracts. Thus, it is said that
people with little or no power of accommodation (presbyopes) are more
prone to cataracts.

>What to do?

Wearing tinted sunglasses reduces your ability to see well in bright light
without them. Most regular glasses block the ultraviolet rays credited
with increasing risk of cataract development anyway. So you wear glasses
of any kind, they're probably filtering out the "bad rays". Even those
without "UV block" still filter out a lot of UV light. There was a
discussion of this on sci.med.vision recently. Several optometrists were
of the opinion that most ordinary, clear glasses provide sufficient
protection.

And remember, it has still not been established how much protection is really necessary in the first place, if any. Some have argued that UV light in small doses is actually good for the eyes, and the experiments showing that you need to wear sunglasses at all times are hopelessly inconclusive. One is optometrist Jacob Liberman, who wrote /Light, Medicine of the Future: How We Can Use It to Heal Ourselves Now/ (1991). He recommends that people chose glasses that TRANSMIT UV to the eyes.

I personally find dark glasses inhuman, and I am not convinced they will reduce my chance of developing cataracts. Ultraviolet light has valuable antiseptic properties, preventing bacterial infection of the eyes and inflammation. I think it is more likely that cataracts can be prevented through good diet than by avoiding UV radiation from the sun.

As Mark Goodes has just recently posted, there's something very nourishing that one feels in the eyes when one is outside. I think part of that feeling of nourishment comes from the effect of full-spectrum -- including UV -- light on the eyes.

> Does anyone know the medical explanation/definition of astigmatism?

According to my Mirriam-Webster's 9th, astigmatism is when "rays from a point fail to meet in a focal point resulting in a blurred and imperfect image." This would make it sound like near- and farsightedness are just special cases of astigmatism.

As the word is most commonly understood, though, astigmatism is the condition where the lens or the cornea (more often the cornea) is warped so that depending on what the angle is, a line will be more or less out of focus. So, for example, a vertical line could be clear, while one at a 15 degree angle could be fuzzy.

Can astigmatism be cured using home therapy? I think so. At least part of what causes astigmatism is the same thing that causes nearsightedness -- strained muscles pulling improperly on the lens or on eyeball as a whole (which may particularly affect the cornea). Also, if you improve your ability to accommodate (adjust for distance) -- the astigmatism will diminish somewhat. I quote from the sci.med.vision FAQ:

:Astigmatism causes images to be out of focus no matter what the distance.
:It is possible for an astigmatic eye to minimise the blur by accommodating,
:or focusing to bring the "circle of least confusion" onto the retina.

This is not true... Looks like you will have to look further in to what astigmatism is. If you are a hyperopic astigmat, both line foci fall behind your retina. The circle of least confusion, of course, lies between these two line foci. If a hyperopic astigmat (or a mixed astigmat) accommodates to bring the circle of least confusion on to the retina, his vision will be best overall. However, if horizontal lines were previously clear, they would now be blurry; vertical lines would also be blurry, but equally with the horizontal lines, not blurrier as when the horizontal focus was on the retina. The dioptric distance between the two line foci will remain the same (in the vast majority of cases - I am an exception, which I will get to shortly), no matter where the circle of least confusion is. The measure of astigmatism is defined as the dioptral difference between the two line foci. Accommodation will not reduce the astigmatism, it will just minimize the blur, and only if you are a hyperopic astigmat, or a lucky mixed astigmat. Accommodation in a myopic astigmat, will of course increase the blur, just like accommodation in a myope will increase distance blur.

Now, why am I an exception? When my right eye accommodates 8 dioptres, I gain 0.50 D of astigmatism. This is meridional lenticular astigmatism, caused by uneven contraction of the ciliary muscle, or uneven tension on the lens capsule by the zonule of Zinn. My left eye does't change.

(again i apologize for my computer difficuloties, your letter of regard follows my reply)

in regards to reducing astigmatic blur with respect to accommodating, the answer is not necessarily so, in fact it is OFTEN not so...

the img progression that i described can be thought of as a fixed piece, the extremes being the two line foci with a circle (the COLC) at the dioptric midpoint (not the linear midpoint) between the two line foci... ina perfect system, the point object produces a point img. that falls on the retina...if you are nearsighted (with no astig) the point img is formed too quickly and falls in front of the retina...further addition of power by the lens only serves to focus light EVEN SOONER and hence place the img even MORE in front of the retina...with farsightedness (no astig) the eye does not have enough converging power, and the point img is formed after the light has reached the retina, forming a point img behind the retina...in this case, power can be added by the lens (accommodation) in order to place the focal point ON the retina assuming you have enough accommodative ability...

having said that, with astigmatism, that focal "unit" can ALSO fall at any of these three scenarios...COMPLETELY in front of the retina (if the patient is myopic in all meridians, ie: both numbers on your astig.prescription are negative--for an optometrist's prescption), OR the unit may fall completely behind the retina for a hyperope in all meridians (both numbers of the prescription positive) OR the "unit" --which is called the interval of sturm, by the way--can straddle the retina...note that in this condition, the COLC can fall infront of, behind, or ON the retina... accommodation can only place the COLC on the retina WHEN IT IS BEHIND THE RETINA AND THERE IS ENOUGH ACCOMMODATIVE ABILITY TO FOCUS IT ON THE RETINA...therefore, myopes--and that is most of your target audience, i would think, CANNOT reduce astigmatic blur by accommodating! ...which was my point about your characterization being a bit oversimplified...

as for the corneal change with accommodation...as i am unfamiliar with the specific article in question, i can only make educated guesses, BUT here goes...accommodtion, presumably is not designed to slter power by it's effects on the cornea, anychanges are like on a micrometer type scale...likely the effect is NOT significant with respect to changing the power of the eye...BUT if it DID in fact change the power sugnificantly, i would wager that b/c the accommodative muscles are in the form of annulus, the changes would be even across the cornea making a spherical change in the lens...spherical changes DO NOT alter the astigmatic need for correction...if you change the greatest power meridian and the lesser power meridian by the same value, the net difference between the two is still identical, and the difference in powers between the meridians is what is DEFINED as astigmatism...

i don't mean to rant and rave, so i apologize if this seems a bit confrontational...i just want to make sure that misconceptions are corrected and not disseminated...thanks for your response...

>Yes.... In fact I have published a paper on the topic. What would you
like to know. It's actually a VERY complicated subject which far too
often is trivialized as an irregular shaped cornea or misaligned optics.

Small amounts of astigmatism are secondary symptoms of visual stress.
When the minus cylinder axis is at 90 degrees the primary problem is an
accommodative disorder. When the minus cylinder axis is at 180 degree
the primary problem is an eye teaming problem. This would be for
amounts less than 1 diopter.

For greater amounts the astigmatism relates to posture. The basic
concept is that sustained assymetries will cause asymmetric development
in the visual system.

Our dictum in behavioral optometry is: Function alters structure.

Hope this helps.

This makes sense.

I have astigmatism of, from memory -0.75×178 -1.0×175 , and I find posture plays a role in my double images.

alex,

[sorry i have not enclosed the appropriate clippings, but my computer is having difficulties]

you have made some erroneous assumptions with regards to whether or not astigmatism lends itself to correction via vision therapy... it is true that in some cases of astigmatism you can accommodate to put the COLC (circle of least confusion) on the retina (but not in all cases of astigmatism)...HOWEVER astigmatism is an error due to shape of structures in the eye, usually the cornea) accommodation does not change the shape of the cornea at all... astigmatism as you have pointed out was oversimplified in the webster's dictionary (nearsightedness and farsightedness ar not specialized forms of astigmatism, though they can be related) but furthermore, your characterization of astigmatism is an oversimplification of the true concept...corneal shape remains constant at all distances, which is why astigmatism persists at all distances...however, a point object will be focused as a progression from a line, through a series of ellipsoids, to a blur circle (COLC), through more ellipsoids, and finally to a straight line oriented 90 degrees to the first...THIS IS THE IMG FOR EVERY SINGLE POINT IN AN EXTENDED OBJECT! depending on the state of accommodation AND the refractive error present in the eye, someone MAY be able to focus the COLC on the retina, such that every object poit forms a blur circle on the retina...this is the clearest possible focus WITHOUT changing the cornea shape, or using corrective lenses...(if this made no sense whatsoever, i would be willing to discuss it further as time permits)...i hope this has been of interest

david.

 >--Alex

Hi,
 This is your statement:

Also, if you improve your
 ability to accommodate (adjust for distance) -- the astigmatism will
 diminish somewhat.

Hence my explanation.

In discussing patient's visual problems with them,
 astigmatism is one of the hardest concepts for patients to grasp. They
 almost always, in later discussions, talk of it as if it were some
 terrible condition, that their eye has "a stigmatism," and are always
 vague about what exactly a stigmatism is (such as if it is some
 communicable disease). Even a mild amount of astigmatism (especially
 if the axis is at ninety degrees (known as against-the-rule, because
 most is at 180 degrees, or with-the-rule) can cause asthenopia (eye
 strain symptoms), as the accommodation control system is a bit
 spun out by the two line foci, and doesn't know where to focus to.
 Printed text has a strong vertical bias, so it is not necessarily best
 to focus the circle of least confusion on the retina.

Cheers!

From usenet.ucs.indiana.edu Sun Mar 19 08:12:19 1995
 From: Ted_Landis@BendNet.Com
 Newsgroups: sci.optics
 Subject: Astigmatism
 Date: 17 Mar 1995 17:40:48 GMT
 Organization: RGNet

I just got some new glasses and I'd like a second opinion.

My old glasses didn't have any correction for astigmatism.

The doctor now says that I have an astigmatism in both eyes, a little
 in the right and a lot in the left. I got my new glasses and now,
 while everything is very sharp, all rectangular objects look like
 sideways trapazoids! If I look at a rectangle on my computer screen,

the left side is about 10% longer than the right side, and the top and bottom lines flow up and down respectively.

The doctor says that this is something that I will get used to and that within a week or so, my brain will adjust the image so that I don't notice it anymore.

While my brain may be able to adjust, I don't know if I want it to. Is this really just a case of over correction of an astigmatism?

Anyone have an opinion?

BTW, the primary purpose of the glasses is to correct my nearsightedness.

Thanks for any help,

Ted

>are adamantly opposed to cylinders.

This is a very difficult question to answer in a short form. I'll give a try, otherwise when we work together, I 'll teach you the mechanics. By definition, astigmatism means one area of space is more blurry than another. The seperation is usually by 90 degrees. In the simplest example, the vertical meridian of the cornea would show more myopia than its horizontal counterpoint. Here is the essence. The person's learning is to begin to see through the vertical meridian. This is the area of space that is the most blurry, and represents the most blurriness in their life. In later discussions, I 'll demonstrate that the vertical meridian has particular psycho-emotional correlates. If my hypothesis is correct, then the lens the person looks through, should accentuate light focusing more on the vertical meridian than the horizontal. The only way this can be accomplished is to increase the astigmatism for myopia, although we can reduce the astigmatism in farsightedness. If you just leave out the cylinder, then the person learns to see more clearly through the horizontal in this example. Granted their eyesight may improve, however, their discovery of the learning they need to get to the cause of the problem is never addressed. This is the distinction between integrated vision therapy and say regular vision therapy or even vision improvement. Phew, that does it for now. All the best, Robert-Michael.

I have pretty good astigmatism. When I tilt my head up wearing computer glasses the screen seems to become more out of focus. Tilting down does not go through as much of an angle, so will not comment on that.

I have very low astigmatism (-0.5,-0.5, 100 axis in both eyes). If I stand straight and rotate the lenses in front of eyes i can see the letters get blurry on the eye chart, precisely the reason why I have 100 degree axis correction. Wearing the glasses and tilting my head on either side does not make any difference to me. Well! if that made objects blurry then why get astigmatic correction at all.

Subject: Re: Astigmatism and head tilt

Status: RO

X-Status:

Alex,

It is a FACT that your eyes rotate and it does change your vision thru glasses.

As my personal problem is hyperopic astigmatism. I can rotate my head and see a definite change. However, binocular fusion tends to correct for the error.

Untreated vertical deviations aggravate the problem since they tend to cause head tilt in many cases. Vertical deviations will can cause the neck strain you describe much more often. It can also cause slow reading, headaches, backache, motion sickness, and neck pain. They are a common problem. Since they cause slow reading and headaches looking at a computer, every patient should be carefully checked for vertical deviations, especially if head tilts

improve or blur vision.

Blur on head tilt is easy to demonstrate, cover one eye to break fusion, tilt your head until blur is noticed. Clinically, you will find more or less equal tilt right to left with each eye. Unequal tilt can be a sign of problems in the correction worn.

This effect is power related, large astigmatic cases or greater vertical hyperphoria will have more noticeable changes, tilts and errors.

The most accurate procedure, Binocular Fusion during refraction, is not common in OD's procedures. It is very rare, if ever, done in Ophthalmology practice.

Common methods to discuss with your eye care provider:

TIB, Turner Infinity Balance is used at UAB with mirrors, each eye sees half the chart. The American Optical Vectographic chart uses polarized, "3D", each eye can see every other letter. It is found at any office that provides binocular vision analysis.

I think its all the more reason to get an annual professional eye examination that includes binocular vision analysis.

On Thu, 30 Nov 1995, Torres Mario wrote:

> How can I know which category does my poor eyesight belong
> in? myopia or stigmatic?

First of all, the word is "astigmatism", which comes from greek "a" without + "stigma" = point. So etymologically it just means "unfocused".

Now then. Myopia means that your eye is incapable of adjusting for faraway objects. The image is projected IN FRONT OF the retina (Hyperopia or presbyopia means that the image is projected in back of the retina for near objects. Yes it does sound counterintuitive, but that's just the laws of optics. With a lens of a given power, near objects are projected so that the screen should be further from the lens, and for farther objects, the screen should be nearer.) In other words, if your retina could be moved up closer to the lens, or if the object were moved closer, the image would be in focus.

Astigmatism means a slight "extra" curvature in the lens or cornea to make the refracting surface non-spherical. The result is that no matter where you move the retina (if you could), or no matter where you move the object, it will be out of focus. Another side effect of astigmatism is multiple images in one eye, especially from luminous objects like the moon. For many people, the effects of astigmatism are different at different distances.

It is possible to have both myopia and astigmatism.

It is also possible to reduce or cure both myopia and astigmatism, by putting your mind into a state of restful alertness, by relaxing the muscles of the eyes, face, and neck, and by keeping the mind, eye, and body mobile, as opposed to tense, strained, and worried. Body affects mind and mind body.

More specific suggestions as to how to do this coming up! Stay tuned! Or, if you have your own favorite mind and/or body relaxation techniques, please post them to I_SEE.

>
> Overall, what is the best method to get rid of these pesky "Eye Floaters"??

People with high errors of refraction tend to get floaters. Supposedly this is from pieces of the tissues of the eye flaking off the coats of the eye, resulting from strain. Actually everybody notices floating bodies from time to time, especially when looking at a uniformly brightly lit surface. Have you ever asked your eye doctor about them? William Bates recommended relaxation as a way to get rid of the symptoms. He thought floating specks were completely imaginary, which I do not believe is true. So I would say, try palming and shifting (see "Bates Method in a Nutshell" on the I_SEE Home Page <http://silver.ucs.indiana.edu/~aeulenbe/i_see.html>) to get rid of your PERCEPTION of the floaters. They'll still be there. If you're concerned about medical implications, ask your doctor.

Okay -- I hope I'm e-mailing this properly....

Based on the following information, I'm hoping someone can either tell me what to start reading or the name of an informed (and obviously *good*) eye doctor somewhere in western Washington.

Several years ago, I went to my eye doctor for an exam. The young assistant seemed frustrated that she couldn't get the result she wanted for that "puff" test (what's that called?), and complained to the doctor "something's wrong!" (which is a really dumb thing to say in front of *any* patient), so the doctor had to come do it himself and reassured her that there was no problem.

I had noticed that my vision had deteriorated significantly in my left eye, which had always been my better eye (I'm nearsighted) and so this was interesting to me. I had also noticed a "stuffed-with-cotton" feeling all around my eye, which I STILL have, and the doctor said it was nothing. This annoys me, since it is sometimes accompanied by tenderness on the skin next to my eye on the inside. Recently (inspired by mildew?) I have had a sore spot on my forehead at the surface (which is really weird) but it appears to correspond with the frontal sinus. Does this sound likely? My upper teeth sometimes feel uncomfortable too on that side. I can't shake the feeling that I can *fix* this. By the way, I did NOT get that prescription filled (for the new glasses) and am still wearing my 1987 prescription (I'm 33). I can still pass the visual exam for a driver's license.

Does anyone know anything about how sinus pressure might affect the eyes and what to do about it? Or whether this might be something else? Thanks!

Subject: Eye Pressure and Myopia
Status: 0
X-Status:

A few quick notes on pressure, the eyeball, and eye problems.

One theory has it that myopia due to elongation of the eyeball is a result of an increase of pressure inside the eye.

This increased pressure has been thought, variously, to be a result of tension from the extraocular muscles, the ciliary muscles (inside the eye), or a disturbance in the salt-water balance. The latter theory was championed by Emanuel M. Josephson, MD in the 1930's. He actually believed that the difference between glaucoma, which is what is usually identified as "complications from high intraocular pressure", and myopia, is merely

in the tissues that are affected. In other words, the cause is the same, but the effect differs according to the physiology of the person. Young people are more likely to develop myopia from high internal pressure, and old presbyopic people are more likely to develop glaucoma.

One thing Josephson noticed was that myopes tend to have low blood pressure (a chief symptom of which is dizziness upon rising). He believed this was linked to the high eye pressure. For this, he recommended that myopes up their SODIUM intake. He had a plan for the treatment of myopia which included salt and Cortin (a blood salt-content regulating hormone). His treatment of glaucoma was essentially the same.

One criticism of Josephson's theory is that myopes aren't usually diagnosed with high intraocular pressure. Josephson replied that what is actually measured at an eye exam is not the intraocular pressure, but EXTRAocular TENSION. This is what is measured with the "puff" device, or tonometer. Josephson said that for glaucomics, the eye has a high amount of pressure near the cornea, while for most myopes, the increased pressure is further back and cannot be measured with the tonometer. Furthermore, the pressure is quickly relieved in myopes by the coats of the eyeball stretching in response.

Which reminds me. There are three little-known authors that have a lot to say about myopia, and whose names are easy to confuse. Emanuel Josephson, MD, is one of them. The other two are optometrists Joseph Kennebeck and Jacob Raphaelson.

Find their books in the bibliography of "Alternative Eye Science" at

It would seem obvious to me you should get your eyes examined.

You must take some responsibility for your own health. You will go blind before the drivers license department will pull your license.

If you wait for symptoms of poor vision you will be in the end stages of Glaucoma before you go for a checkup. Glaucoma should be spelled "blindness".

Be careful to select an Optometrist or Ophthalmologist that will both listen

to your complaints and explain the results of an examination. Beware of bargains in eyecare and parachutes!

FYI Increased intraocular pressure is one sign of Glaucoma, your symptoms could also be related to sinusitis or thyroid (Graves) disease. Pain or discomfort with eye movement can be a sign of several other eye diseases which should prompt a medical eye work up.

On not wearing the most accurate prescription: I have had patients with undercorrected vision problems seek my attention and get an updated prescription to solve Headaches and other minor ocular discomforts like eyestrain. It was too bad they spent excess time and money to have a complete neurological work up. Not to mention the emotional stress of the CT scan. The most common conditions that cause head/eye aches are uncorrected hyperopia, astigmatism, hyperphoria, and suppression of normal binocular vision. Myopia rarely causes these problems, yet thats what the "screening" vision tests are best at detecting.

I ask each patient of mine to be part of the eye care team. They must protect their eyes with diligence 365 days a year. I get to see them only one day at a time and often only once a year. Goofy things should prompt at least a telephone call to your doctor. Early intervention is critical in all areas of medicine. Eyecare is no different.

Vic,

You're absolutely right that for some people 20/40 could be very dangerous for driving at night. That really hasn't been a challenge for me. Since I've been "sunning" I've noticed that my night vision has improved dramatically. I used to regularly "flash" oncoming cars at night thinking they had their brights on - most of the time they didn't. Now, even if I know someone has their brights on it doesn't bother me a bit!

I've lived in the same town for all my life, so I'm very comfortable and familiar with everywhere that I drive. Normally, night or day 20/40 is easy for me. However, when I'm going out of town on business, or to a place I've never been before, I always wear 20/20 correction.

I think Walt's estimates of eye-muscle relaxation during sleep are --
what shall I say -- strained?

This very morning I woke up before sunrise. I looked out the window and,
by the streetlamp light, things were very clear. I looked into the closet.
Things were very clear inside too. My eyes felt fresh and relaxed. Then I
went back to sleep. When I woke up again, the sun had risen, light was
pouring through the window, and my eyes were very cramped all over and
vision was blurry.

It seems sleeping in total darkness makes vision better when you wake
up while sleeping in bright light makes vision worse and even gives you
eye cramps. This is probably due to the iris responding to the light.

Here three ways carrots are good for your eyes:

1. Vitamin A. Carrots contain beta carotene, which your body converts into Vitamin A. Vitamin A is a major component of the retinal "emulsion" known as visual purple, which picks up light. If you don't get enough vitamin A, your night vision suffers.
2. Potassium. Carrots contain lots of potassium, which is good for the muscles of the eyes. Lack of potassium leads to muscle cramps.
3. Crunchy! Eating raw carrots is good exercise for your jaws; it relieves facial tension and with it eye strain.

EyeCare Connection page <<http://www.pacrain.com/~eyecare>>, run by I_SEE
member Larry Bickford <eyecare@pacrain.com>.

EATING YOUR VEGETABLES MAY LOWER RISK OF AGE-RELATED MACULAR
DEGENERATION (ARMD)

Evidence continues to mount supporting the theory that at least two carotenoids, lutein and zeaxanthin play a key role in ARMD, a condition which causes decreased visual acuity and blindness in older adults. Researchers at Harvard Medical School compared the dietary habits of patients diagnosed with ARMD to those with other eye pathologies but without ARMD. They found a direct correlation with increased consumption of carotenoids and decreased risk of ARMD.

Science has long accepted the role of beta carotene's related compounds in retinal neurological processing, but recent studies indicate that some of the other carotenoids may have more profound effects on the aging eye. Along with the antioxidant minerals selenium, chromium and the polypeptide glutathione (and the related amino acid glutamine), these nutrients may provide the key to maintaining better visual function in later life.

Lutein, zeaxanthin, as well as beta carotene and xanthophylls are found in dark green leafy vegetables primarily in the cruciferous family. These include broccoli, cauliflower, cabbage, Brussels sprouts, kale, collard greens, mustard greens, and spinach. It appears that just two or three servings a week provides significant nutrient levels.

Hey, why don't you look up some herb suppliers in "The Herb Book" by John Lust (every library and almost every bookstore has it)?

Tea is better, it's true -- and it tastes so good!

Try eyebright too. I've been reading about it in some Russian herbals lately. It's called "ochanka", and it has great many uses besides helping your vision (regulates the function of the digestive organs, in particular).

> Your comments on bilberry tea intrigue me. I have never
considered the tea, probably because I have never seen it
advertised.. My wife and I are taking the 375 mg capsules,
which the bottle states may be opened into a glass of warm
water to make a tea. But the capsules are so easy to take,

why go to the trouble..From this labelling I assume I am taking the crushed leaf type.. I am checking around to see if I can find the extract type as it seems most of the medical research has been done using the extract. I am finding it very difficult to find out any trustworthy facts on the bilberry that is available. The recent report made available here, written by Paul Bergner, stated that one type of leaf had a detrimental effect on the liver. The type that I trust the herb sellers are putting out is the "Vaccinium Myrtillus" or more commonly referred to as V Myrtillus..This Type appears to be the only type that has been researched..

You are right that it is rather expensive, as the first bottle I bought at the local vitamin dispensary, that I am on the least precarious belief level with, cost me twenty dollars for 90 capsules. I have since found a catalog sales outfit that during a special sales period, allowed me to get them for ten dollars per 100 capsules. We started taking bilberry about two months ago with very satisfactory results..and now plan on giving it at least a 6 month trial. We started by taking 3 capsules a day for about a month, then noticed as researchers have noted that we were both feeling the diuretic effect of the bilberry so we have cut back to 2 a day and seem to be getting the effects we wanted on our eyesight..

As for concrete results; I had my regular eye exam about a month after we started the bilberry.I have an exam every four months because of a 15 year battle with glaucoma. I got the lowest pressure reading on both eyes, that I have recorded over the past 3 years.Not by much, but the lowest reading in three years and I was shocked because the only thing I was doing differently was the bilberry..I had the tech double check since I have had wrong results before, But he duplicated the first results so for the time being I have to assume they were accurate. The next check a couple of months from now will be the clincher, I hope. My wife who has no glaucoma problems went for her normal yearly checkup and asked for a new prescription so she could get her old glasses replaced.. When the the lady that was measuring up her eyes for a fit of the new glasses, looked at the data, she acted very surprised and blurted out "Your eyes have improved since the test you had 2 years ago". Eyes of people your age don't improve but deteriorate a little year to year. (Our age is a secret, but we did both retire a number of years ago.)

Our personal observations are; I am not wearing my glasses around the house, which I have had to do for many years. I use a set of reading glasses occasionally, but find some times I can read comfortably without them. This is a new and novel experience. I have set up an eye chart here in our computer room, which allows us to make random checks, and my wife has noticed that her eye that does not have an interoc in it, but does have a developing cataract, is reading the chart better..I don't know whether this can be ascribed to improvement in the cataract or to improvement in vision intensity..Time must pass before we know.. Hope this rather lengthy letter may allay some of your apprehension and prove to be of some help to you.

N hmmm maybe thereis an export market for this stuff?

Dear Vic,

Considering how impossible it is to find this in the store, I
sure think so! I feel like I've been to every single health
store in NYC (and there are LOTS) but no one knew a thing about
the tea.

I hear that this is the best form of bilberry as well as the
cheapest. (Cheapest is fantastic but best is the most
important so since its the best I'd want it even if it was the
most expensive). It is also suppose to taste great.

Bilberry jam was said to improve the night vision of Royal Air Force
pilots in World War II -- that's what all the books say. Modern
experiments confirm the beneficial effects of bilberry extract on the
retinal capillaries. The extract also appears to help in cases of
glaucoma. Unfortunately, no one I ever talked to has ever been able to
find this jam in stores. At the health food stores, you can get pricey
bilberry extract pills, but there too, no jam.=20

Well, today I found something close... bilberry nectar! It sells for \$7.75
for for a 500ml (17 oz.) wine-style bottle at the local health food store.=
=20

It's imported from Switzerland. The ingredients are "Juice from
organically grown forest bilberries, spring water, fructose." It also=
says "Enjoy 1 glass of juice before each meal as a healthy addition to=
your diet."

I tried some. Not bad! Like grape juice. I doubt I'll be able to afford=20

one glass of it before each meal, though. A nice alternative to wine, though.

The company that imports it in the US is

Bioforce of America, Ltd.
Kinderhook, NY 12106

In Spain...

Bioforce Espa=Fla
Flor de Loto S.A.
E-08021 Barcelona

And here's what looks like the Swiss Address..

I wish I could give you some accurate answers, but I am neither a doctor nor a vitamin expert...My problems were not one of retinal disfunction so I have not done any vitamin research toward this problem. Having said that, I might generalize a bit...If I was to make one fairly sure suggestion it would be=7F to first try Vitamin "C" in dosage levels as high as you can stand with out stomach upset. I think Doctor Linus Pauling was right in his assessment of C..It is needed by every cell in the body in rather large amounts. I have never heard or read of any=7F bad side effects from large doses of this vitamin, except the problem of loose bowels when too much is taken.

There are vitamin mixtures in every vitamin store and from every

mail order supplier specifically for the eye..Each company has their own brand name..One calls it OcuVite, another refers to Eyetamins. I have looked at the makeup of these and they are all very similar, invariably containing Carotene, C and E plus several trace minerals. I have a friend who swears by these, as having helped his eyes, but I don't think he ever told me what his problem is..

I noticed you said you are taking 5,000 units of A...I personally prefer taking the Beta Carotene and let the body produce the A it needs from the carotene.. In substantial doses of 25 to 50,000 it is supposedly safer and with fewer side effects..

Right now I am investigating the eye benefitting effect of Bilberry.. The claims for this herb are interesting, but the claim that it strengthens the capillaries and improves the blood flow is the one that intrigues me the most.

The deterioration with age or disease of the capillaries in the retina with their vital enriched blood flow, worries me more than any other factor in protecting my eyesight...How will I know if it accomplishes this, is something I don't know at present. But If over a 6 month period I find that my vision is truly benefitting from the use of it, I will probably assume that it is the vital capillaries that have benefitted.

best regards:

Over the past months there has been discussion and questions about bilberry. I became interested myself because with the volumes of mail I receive I sometimes have spent 12 hours at the computer. My vision became so blurred I had to use glasses to read, and only had used glasses for night driving.

Didn't know much about bilberry but picked up some at the health food store. Also put sea salt on my computer because a journalist told me it would cut down on the radiation and help.

Well its been about a month or so now and I notice my vision is no longer blurred when I read a book. Yesterday I finally saw an ad in the paper that gave a number where you can get information. It's 1 800 -818-9131. Perhaps they send out information.

It is interesting that what caught my eye in the ad was MACULAR DEGENERATION in large print. Then they showed some blurred tulips and said "Before it makes your world look like this... you should read this: Here's what the ad said:

"Today, 83% of eye care professionals recommend nutritional supplements like Bilberry 2020 for the eyes, even for patients concerned with macular degeneration and cataracts.

Providing specific nutritional support to the structure and function of

the eye, two Bilberry 2020 caplets a day can help strengthen capillaries and inhibit deterioration. In a recent pilot study of 100 people taking it as a supplement, 55% reported benefits after four weeks ... and 78% after eight weeks."

So for those looking for more information on Bilberry I hope this information number helps.

Regards

Betty Operation Mission Possible

P.S. I have been exceptionally pleased with its use.

> Pankaj Shah

I have used eyebright herb on several occasions as a tea and as an eyewash. It was particularly expensive -- over \$50 a pound (typical herbs are \$10-15/pound).

My most amazing experience in myopia reduction occurred after drinking eyebright tea once a day for I think two or three days. But at that time, I was also doing intensive patching therapy. I seem to recall a certain tingling sensation (different from the sensation sometimes that comes from practicing distance viewing) and a "strong" feeling in my eyes after taking the herb. This all wore off after several days. I also stopped doing the patching. As you can see, not a very controlled experiment!

Eyebright is supposed to relieve eyestrain, and to the extent that myopia is caused by eyestrain, eyebright will reduce myopia.

I think it's worth it, if your health food store sells it in bulk, to try say \$2.00 worth, which will yield a few cups of tea -- enough so that you can see if it does anything. You can also try it as an eyewash: make tea, let it cool off (!) and then put some in an eye cup (available at the pharmacy) and swish around. This may be even more effective than drinking it.

That's eyebright. It's sold in capsules, but it tastes great as a tea,
too. There's an herbal tea blend called "Bright Eyes" that contains
eyebright, and the dried herb is also available in bulk at health
food stores.

The book /Prescription for Nutritional Healing/ by James F. Balch, MD,
and Phyllis A. Balch, C.N.C, (Avery, 1990) says that the entire
plant except the root has medicinal properties, and it contains
(quantities not given):

bitters	inositol	volatile oils
PABA	sulfur	tannins

Vitamins: A B3 B5 B12 C D E

As for actions and uses of eyebright, it says "Used as eyewash. Prevents
secretion of fluids and relieves discomfort from eyestrain or minor
irritation. Good for all eye disorders."

Don't ask me how the B12, which is only supposed to be in animal and protozoan
products, got into eyebright.

According to /The Herb Book/ by John Lust, eyebright is both an
astringent and a tonic.

I've never heard of a clinical study being done with eyebright.

Muscles do not normally bulk up unless the training chosen is directed that way. To bulk up you typically do minimal repetitions with the maximum weight possible. As there is no way I know of to add weight to an eye exercise, I do not believe you need to worry about this. Consider also, the case of runners, swimmers, cyclists and other heavy-duty exercise athletes where continued use of the muscles rather than explosive use, as we associate with weight lifters, is used. The eye muscles are used continually, more along the lines of these athletes.

Another possibility though, is that muscles can become permeated with fat if they are not exercised. I don't know if this has ever been checked in the case of eye muscles.

This reminds me of two things:
1. An ancient Chinese method to temporarily improve myopia: one goes to sleep
flat on his back, with heavy little bags filled with sand placed on his
closed eyelids. After several hours of sleep (provided you have whatever
training it takes to maintain this sleeping position), you wake up with
temporarily flattened corneas and improved vision.
2. In Eastern Europe, magnets for medical use were patented for several

conditions -- I forget which specifically, but I even own a pair of magnetic earrings which, on a number of occasions, have helped my eyestrain and related headaches. (After discovering palming I haven't used them because palming works better for this purpose.)

There was a post on misc.health.alternatives recently that claimed lying down with circular magnets resting on your eyelids (time length not specified) was a great help with presbyopia. My other magnet experiences lead me to believe that this may be worth trying. Has anybody here had any experience along these lines?

Not sure if it's quite relevant, but I certainly know that inappropriate (for me) use of colour in printed material can make things very hard to read. Now that publishers and advertisers have the technical ability to mix colours to their hearts content, some of them seem to think they have to do so, regardless of its effect on readability. Things that I find next to impossible to read are:

Black print on dark red background
Black print on dark blue-purple background.

(there are probably others - those are the ones that come to mind)

"fade in colour" (or whatever the technical term is) just makes things worse, as your eye can't settle on what the contrast is supposed to be.

Labels on certain food and vitamin packaging are rather prone to this; irritating as the print is often small.

>Help!

I use a computer screen around 8-14 hours a day.
the things to take note are. sit near a window with a nice distant view.
try to spend more time looking out the window then your screen.

usually what happens when you stare at a computer screen is you develop
a good fixed stare. so you want to reverse this process and do things
like moving your eyes around the socket as often as possible.
also your eyes have a tendency to dry up when staring at a screen, and
posture caves in. so you want to remember to blink often, and get a decent
chair to sit in. I have a chiropractically approved chair I bought for
myself cause work didnt want to.

since you are catching this at an early stage all the standard bates
techniques have a very high chance of reversing your problem quickly.
eg palming, sunning. shifting. etc.

Bert,

Here are a few ideas to discuss with your healthcare practitioner when you visit him/her to diagnose the problem. Of course you don't want to try everything at once, but one or two of the ideas may prove useful in finding a solution to the problem.

1. Computer setup

- a. Ergonomics -- The setup of your workstation is very important. Even though the setup may not have changed for a long time, it could be a contributory factor to your problems. As a computer professional you know that one way to solve a problem is to logically, in a step-by-step fashion, go through each possible cause. So, **please** take a little bit time (and it doesn't take much) to check and adjust the height **and** position of the keyboard, monitor, chair, and mouse. If you need more information about the proper setup, please contact the occupational health department in your company or email me and I can provide the information I have.
- b. Lighting -- The can be another contributory factor to health problems which develop with computer use. Once again, even if you have had the same lighting for years, it can still be a contributory factor. If you are using typical fluorescent lighting, for an 8-hour+ day, I cannot too strongly recommend getting different lighting. The spectrum from fluorescent lighting is quite a bit different than natural sunlight and is not only bad for the eyes, but bad for health in general **if** one spends a considerable length of time in that lighting.

I recommend going with natural spectrum light bulbs such as Vita-lite. The natural spectrum fluorescent bulbs tend not to be as bright as many typical fluorescent bulbs, so you may have to supplement it with an incandescent bulbs. Even if you have to just use incandescent bulbs, it's better than fluorescent lighting as long as you use enough lighting so as not to be in the dark. Another light to consider is an Ott Light which is about as close to natural sunlight as you can get because it is full spectrum and includes an ultraviolet light. Just be sure that it isn't too dark, i.e., programming by computer light.

Below are some lighting companies. Also, I recommend contacting the OTT-Light company and asking for information about research by John Ott. He performed decades of research on the health effects of different lighting and computer monitors on plants and animals.

- c. Computer Monitor -- Color monitors tend to have a much stronger electric field in front of the monitor than a monochrome monitor. Your computer monitor should meet the Swedish standards for magnetic and electric fields. Check with the manufacturer and/or your occupational health department (which can sometimes perform on-site measurements). You can also purchase a measuring device from Safe Technologies (see below) and do the measurement yourself.

The old Mac RGB monitors used to have an extremely high magnetic

field in front of the monitor. Their newer RGB monitors (since a few years ago), meets the Swedish standards. There are alot of subtle changes that occur from exposure to EMF (e.g., changes in blood-brain barrier permiability), such that if you are a computer professional and spend 8 hours a day in front of a computer, it might be a good investment to get an ultra-low magnetic and electric field monitor. The electric field produced by today's monitors is a big problem (in 8-hour/day exposure) for many people in my opinion, especially those people with chronic immune system disorders.

For many years, I had a monitor from Safe Technologies Corporation. It produces a magnetic field at approximately 1/10 the Swedish standard and cuts down the electric field in front of the monitor to almost zero. It helped me to be able to work eight hours in front of the computer (with breaks) without eyestrain. It costs more than a PC SVGA monitor, but about the same as a color Mac monitor, at least when I bought it.

Another option is to get a NoRad shield that cuts down on the electric field significantly. I would stay away from the cheap glare screens which don't really do anything as far as the electric or magnetic fields. One scientist I have spoken to believes that the positive ions put out in front of the monintor attach themselves to particulates in the air. When those particulates get in the eye (as they generally do), they are more irritating because of the positive ions.

Safe Technologies Corporation
145 Rosemary St.
Needham, MA 02194
USA
(800) 638-9121, (617) 444-7778

They sell extremely low magnetic field (1/10 Swedish standard) and electric field SVGA monitors. The monitors a brand-name monitors that are specially modified. I bought one of their monitors and it is many times easier on my eyes than any other one in our department.

They also sell "zero" radiation monitors, but they are more expensive.

NoRad
1549 11 St.,
Santa Monica, CA 90401
USA
(301) 395-8800

They sell a shield that goes over the screen. It cuts down most of the electric field and some of the magnetic field that usually reaches the computer user.

Another thing to watch out for is the crispness of the letters on the monitor. This is especially important with color monitors since they use three electron beams to produce images on the screen and therefore the letters will usually not be as crisp as on monochrome monitors (even if you use black & white letters). Some recent monitors such as the Apple 21-inch color monitor was horrendous (in many cases) for focusing the letters. When I brought our department's 21-inch monitor in for focusing, there were many others who had returned their monitor because of this problem.

Even lettering which is only slightly out of focus or "blurry" (i.e., not crisp) can cause problems (e.g., eyestrain, headaches, etc.). This is not something to get paranoid about, but it is a good idea to check and compare to other brands of color monitors in the company (or friend's monitors) to see if there is a problem. Another thing you can do is swap monitors with someone else and work with it for a while to see if you find your condition improving.

Finally, I have heard that monitor refresh rates can effect people if they are set wrong (or something). I don't know much about this. Perhaps someone else does? Whatever the case, switching to another monitor for a while (especially another brand) will help narrow down the problem.

2. Air

When I lost the use of my Safe Technologies ultralow magnetic and electric field monitor, I went out and bought an air filter/negative ion generator. It was well worth the cost in my opinion. No longer am I working for 8 hours, breathing stale, "dirty" air and being bombarded by positive ions. If you can't set up a low-electric field monitor, I highly recommend getting a filter/negative ion generator. (Even if you can get such a monitor, it still might be a good idea.) Working in a "positive ion environment" for 8 hours a day is a bad idea in the long run in my opinion.

In addition, consider whether there is a possibility that the air quality in your office is bad or has worsened. For example, did a carpet get installed in the last year at work or at home? Is the air too dry? Are you working or sleeping in a dusty environment? Have you changed your bedding recently (e.g., sheets, quilt, mattress, etc.). Some bedding and furniture products are treated with formaldehyde (even some "all cotton" "natural" products). Investigate possible air quality problems in places where you spend considerable time such as sleeping and at work. Yes, air quality problems can lead to health problems, including vision problems in my opinion.

There are many different brands of filters/negative ion generators. Some produce too much ozone to spend time around while running. Others have worthless filters. The filter I bought not too long ago is working very well and I recommend it for high quality at a reasonable price.

N.E.E.D.S.
527 Charles Ave.
Syracuse, NY 13209
(800) 634-1380
AllerMed Airstar 5c

3. Diet

If you are having vision problems, the first thing to consider as far as food and nutrition goes is whether you are using aspartame/ NutraSweet in any of your products (soda, gum, cereal, vitamins/ supplements, pharmaceuticals). Aspartame is notoriously bad for the eyes and bad for health in general, especially over the long-term.

Beyond cutting out aspartame, a junk food diet or a Standard

American Diet (S.A.D.) will contribute to health problems in the long run. You may want to investigate *gradually* moving towards a "natural foods diet" such as that described in books by Annamarie Colbin ("Food and Healing" and "The Book of Whole Meals"). It will pay off in the long run and might help any eye problems.

4. Stress Release

Stress can definately be a factor in eye problems. I am sure that Alex has mentioned the relationship between stress and the eyes. If you are doing eye relaxation and improvement exercises, you may want to continue that. The following ideas have helped me in the past:

- a. It is very helpful to try and create a ***routine*** where you take a regular break every hour for a couple of minutes to relax the eyes. You can use the palming relaxation technique or other relaxation techniques that you can get from many of the eyecare professionals on this newsgroup. Email for more info. Also, I strongly recommend taking a 10-15 minute break every 2 to 3 hours. Try going outside in the sunlight without glasses or contacts (if possible) and either think about something fun or focus the mind on taking deep breaths. Thinking about computer stuff for 8+ hours a day can be a drain and stressful. Contact aeulenbe@ezinfo.ucs.indiana.edu for extensive information on taking care of your eyesight.
- b. Take a yoga class and develop a short yoga routine. It is best to take a class so you get the poses correct. A short yoga routine is a very good way to keep daily stresses from building up over time and leading to health problems.
- c. Perform a short breathwork routine. This can be a good way to increase energy and release stress, especially stress which is held in the body around the diaphragm area. I recommend the short 5-10 daily routine detailed in the book:

Conscious breathing
by Gay Hendricks, Ph.D.
Bantam Books, c1995
ISBN 0-553-37443-5

- c. Get a moderate amount of aerobic exercise (perhaps every other day), but not too much. By the way, swimming in a chlorinated pool can be hard on the eyes for many people.

5. Other

Sometimes, an herbal eyewash can be helpful. One popular eyewash is making eyebright tea in real spring water or distilled water and putting the *cooled, room temperature* tea in a bowl. Then put your face in the bowl and open up one eye at a time. Move the eye around by looking in different directions. Some people make compresses for the eye by dipping a cotton cloth in the tea and putting it over close eyes for 10-15 minutes. There's a bunch of other herbs that can be useful. Check with your local herbalist.

There are a bunch of other possible contributory factors, but it would take a more detailed description of your case and health & lifestyle history to narrow the other less common cases down.

Best Wishes,

- Mark

-----

- What's new?
- Introduction
- Use
- Some PRETTY IMPORTANT hints
- Wanna print?
- Final comments
- History
- Disclaimer
```

```
What's new? :
```

New to v2.5

-Renamed Kay Pictures to Pictures (more correct use)

-Added two more possibilities in the Pictures: Food and Animals (now Animals

is

as default), there's a little combobox at the bottom from which you can choose the

mode you need.

-Fixed the clipping of the Symbols in the Pictures. Yay!

New to V2.1

-Removed the ruler of the printed version (Unnecessarily distracting, check

the

"Wanna print?" section)

-Made the Tumbling Es square so no height guess is possible.

-There were no 'Z's (!!??). Added 'Z's.

-There were 'W's. Those are forbidden in a Snellen Chart (some rule).

Erradicated

'W's. ('M's have the same trouble, but they were erradicated from the 2.0 on).

still

-Fixed a bit the Pictures (some of them got cutted by the right side, and

still

happens regretably.. I don't know how to fix this, so if anybody has an

idea...)

New to V2.0

This version has a lot of updates, I'll list them below:

- It's now possible to print

- Red underlines can be placed in any chosen row by just clicking on it

- 8 position tumbling Es were eliminated to be replaced by Cs (Landolt Cs)

- A new cool intro and loading screen

- A much better interface

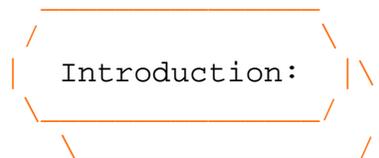

- Fixed the low performance bug of the last version (?!)

- Totally reprogrammed for Flash MX!(faster, printable, less sized player download, etc.)

- Landolt Cs chart added

- Pictures chart added

- Renamed Randomly Oriented Es to Tumbling Es :)

A Snellen Card is something that gets old after some time if you have an specific one. This starts to become a problem when you remember every line without even looking at it. That happened to me more than once, limitating and falsifying my advance, that's why I've created this random letter Snellen chart.

This chart not only generates random snellen charts but also Landolt C's, Tumbling 'E's and Pictures in different flavors.

Enough introduction, time for some handy details.

First, it's very probable that you need not much documentation cuz the "program" is very WYSIWYG (dumbass-proof) and however you (closely for sure) know how to use a Snellen card. This version anyway has got some important changes in the interface so I'm anyway going to explain briefly the use of this program and, later, give you some PRETTY IMPORTANT and useful HINTS about this program. But let's go first for the use instructions:

Use (both on-line and off-line):

Load (need Shockwave for this, you can download it from Macromedia's site or just try accessing the Snellen card, if you don't have the plug-in, automatically it'll take you where you can download the Shockwave Player),

- First, there's a button called "Change Characters" that's used to cycle through infinite random combinations.
- Second, there's also a checkbox called "Rounded Font", this checkbox is checked by default but if you uncheck it, you see the Snellen chart in a more square font, this is, Arial. If you check it again, it'll go back to the Courier font.
- Third, by clicking on any row of any mode, a red underline will appear, click again and it'll disappear.
- Fourth, there are four tabs, each one corresponding to the Traditional Snellen chart ("Traditional" from now on), the Tumbling Es chart, the Landolt Cs chart and the Pictures chart. Right now, if you see the normal Snellen screen with lotsa different letters, you are in the Traditional tab. Click the other tabs to access to the other modes of this Ultimate Snellen Chart.
- Fifth, for the Pictures, the default is Animals but there is a little combobox in the bottom of the "Pictures" section which lets you choose Animals (duh), Food and Symbol.
- IMPORTANT ABOUT PRINTING: when the Print dialog appears, in the pages to print where it says "Pages 1 to 5" or something like that, don't leave it that way, instead use Selected. Do this ALWAYS every time you print.

Off-line use: just unzip (if you're reading this, probably this step has already been done) the file somewhere on your disk, go there and open the html with your favourite Browser (with the "Work Disconnected" kind button checked if it isn't already) and you're done!

I bet most of you won't read all these hints. I don't wanna bore you, so here are their importance levels:

[1]: MUST read

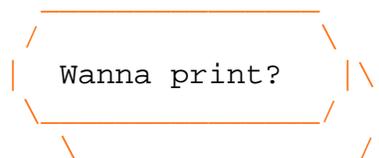

- {2}: Important
- (3): Just a hint

- [1] If you have Internet Explorer, use the Full Screen (F11 key) while using it. If you don't, see if there are any Full Screen button somewhere, if there isn't, consider having IE because it'll drive you mad to use it on a smaller screen.
- [1] When printing, when the Print dialog appears, in the pages to print where it says "Pages 1 to 5" or something like that, don't leave it that way, instead use Selected. Do this ALWAYS every time you print.
- [1] If you have a 14" monitor, use it at 800x600 for real size reference. I've made it that way mostly because it was originally designed for personal use (and left it because it's the most common monitor and resolution). Also, I've been told that it's almost correct in 1024x768 in a 16" monitor.
- {2} Else, if you don't have a 14/16" monitor or you cannot use the 800x600 / 1024x768 resolution, not everything is lost, there is a way to get ahead: first, measure the big first letter (initially an E) in inches, and, if you use to step at 20ft (*), multiply that number for 17.391 and that will give you the distance you should stand at measured in feet. If you use to stand at 10 ft (*) (mainly for lack of vast space which is my case and, I imagine of many others) the multiplier to use would be 8.695 (see it's the half as 10 ft is the half of 20 ft). I've been testing it, sizing it at distance as good as I could in two different scales and everything seems to be in order.

(*): Of course, the choice of the distance will be fixed to your ultimate objective, if you choose to stand at 20 ft, your objective will be the 6th line, otherwise, if you choose to stand at 10 ft, your ultimate objective will be the 8th line and so on

- {2} If you have a glass protector (those for radiation that darken the screen), take it away while reading. Also the brightness and contrast of the monitor will affect, but that depends too much on the monitor, see what fits better to you but I recommend you to put the monitor on the max contrast and a reasonable brightness.
- (3) If you do this daily and take note of what you see to compare it when you're nearer, I mean, you stand far, guess what the whole Snellen chart says, taking note of that "prediction" for later comparison when you're nearer to the screen (that's the way I do it), it's VERY useful to have one of those toys called "Magic Slate" or like, you know, those ones that you can draw and erase and draw again. It'll become a good partner if you get accustomed to use one of them.
- (3) Try to avoid looking at the screen after clicking the Change Characters button or you will be cheating ;)
- (3) If you stand at 10 ft, your last objective will be the 8th line, that may be a problem because that line is a bit beyond the reach of the

screen (at least in the common monitor/res.). There are two solutions for this kind of problem: go back to the computer to scroll the bar down or (what I found to better) move the scroll bar before you go far. To calibrate it for everything to fit and still not look directly at the screen (believe me it becomes a problem), you can use the first reading at the top left, the one which says "70 ft - 21 m", scroll the bar until this line disappears almost completely and that's it, the page is aligned to cover from lines 1st to 8th (well, not much of the 1st, but you can still distinguish what is it; however, if you can't see that letter, you won't need to scroll the bar down as you won't see that "extended rest" anyway)

I've been thinking alot about this addition as it is very important that you print in the way outlined here:

When you select what you want to print, you click on the icon that appears in the top left corner and when the Print dialog appears, in the pages to print where it says "Pages 1 to 5" or something like that, don't leave it that way, instead use "Selected". Do this ALWAYS every time you print.

About the size it'll be printed, it should be ok for any paper which has the width sized as an A4 paper which is the most common one. However, to check sizes, measure the first letter, it should be of about 1,25" / 3,2cm.

The print options however aren't much, so if for ANY reason it doesn't fit, you'll have to press the "Print Screen" key on your keyboard, load it on any Image edition program, paste in a new image and print it from there. And use that size (1,25" / 3,2cm. for the first letter for reference to change the paper's print resolution to fit the real size it should have.

Well, that's about it, I have nothing else to say by the moment, if you have ANY ideas or comments, insults or money ;) please contact me. Also about any other thing like this that could come in handy.

Many people did so and they made it by mail asking, so you see, you too can become FAMOUS by throwing a good idea ;)

Seriously talking, if you do any cool suggestion that makes this program to get better, I promise I'll put your name in this "Hall of Fame" :)

Hall of Fame:

Thanks to Harry Incs, the one who gave me the idea of the "different resolution/monitor problem" solution and the one who inspired me to write a longer version of this document (to be honest, to add this all after the Introduction :)

Thanks to Rajiv Bhushan for one, the Arial/Sans Serif idea, and two, the Tumbling E's chart.

Thanks to Ryan Roberts, he gave me the suggestion of the printability and corrected me some of the errors of the 2.0 version.

Thanks to Zvi Zoblin, he gave me the food and animals fonts to use on the Pictures. Remember that you have this version (2.5) on your hands because of him.

Also a call to anybody who has the knowledge: I've read somewhere that there are some devices that "teach" you how to control the muscles of your eyes. I'm pretty sure that such a thing would be a VERY BIG help to all of us. If you do know how those machines work, I mean I'm sure they show you something and tell you to do certain things and voila, you've learned to control your eye muscles. THAT is something that could be very possibly recreated in a computer program that I'm sure I could do. If anyone has the knowledge about how that works, tell me and I'll do a program that does the same thing except that this would be for free.

So the "Final Comments" weren't final really, huh? :)

Well, I know that, but the History of the Program is the most boring part, together with the "Disclaimer" thing, so I've left them for the real end ;)

11-12-03: Inspired by Alex Eulenberg, I reconverted the txt file to html so that you can browse it easier as well as change the text size and such stuff.

26-11-03: A new surge of enthusiasm inspired by Zvi Zoblin. Corrected all of the errors of the beta and remade the screen now with a kewl logo. Added food and animals in the Pictures and fixed the so disturbing clipping from the symbols at the Pictures.

??-10-03: Made 70% of the update to the new version with tons of bugs to correct.. things that I didn't get why happened.. that and the lack of time discouraged me a little on taking it to final.

- 22-04-03: Another mail by Ryan Roberts correct some of my errors of the 2.0 version. I corrected these errors and here it is updated to a 2.1 version as minimal things were changed. Sorry for the big delay but I've just got into Algebra studies right on that moment and couldn't get it fixed before, plus some more trouble that messed things up more than I expected (it didn't want to obey my commands :)) but victory came and here it is updated.
- 18-03-03: Inspired by a mail from Ryan Roberts, the Ultimate Random Snellen Chart Generator v2.0 is done. Recoded the whole thing for Flash MX, added a print button, underlines, Landolt Cs and Pictures.
- 06-02-03: Finally the "Ultimate Snellen Chart" is made. I've called it that way because it has at least to my knowledge all the charts possible all in one in a 30kb file, that is less than a .gif image with a chart :)
- 02-02-03: The E chart, at last working, was going to be sent separate as the Arial Snellen chart... but, I noticed this was starting to get messy as everything was in different places, different files, with very like READMEs but having a different meaning because they were all different programs.. a total mess. I've started that same day to develop a version that mixed all the characteristics I've been adding.
- 26-01-03: Again, Bhushan gives me another idea: the one of the randomly oriented E's chart. I start to develop it having a painfully bad luck with it's progress
- 23-01-03: Rajiv Bhushan gives me the idea of an Arial version of the chart. Version updated, this one was going to be added as another chart. The only copies of this version was for Rajiv Bhushan and for I-See.org's Webmaster for upload.
- 04-12-02: Harry Incs gives me the solution for the monitor resolution problem with monitors of other sizes than 14". Updated the text with a cute (IMHO) ASCII file with a lot more information than before.
- 22-11-02: The very same Random Snellen chart was sent to I-See.org's Webmaster, Alex Eulenberg for everyone's use. This version had a very crappy txt within :)
- Before: I've created the first Random Snellen chart for my own that personal use.

Disclaimer

This software is WhateverWare and you're able to do whatever you wish with it. Throw it away, spread it as you wish, steal it, claim it as yours and become rich and famous (well, not rich, that should belong to me ;)), or whatever. Seriously talking, if you're SO KIND, keep it with all the files in, this one included, you'll be doing a favor to the whole humanity! ;) (oops, sorry... I forgot I was being serious) also, if anyone has any problem, In my all so humble oppinnion, I could be of help.

Ultimate Random Snellen Eye Chart Generator v2.5

Due to the popularity of the Ultimate Random Snellen Eye Chart Generator, to conserve bandwidth, we request that if you like the Eye Chart Generator, that you download a [ZIP Archive](#) of the generator for off-line use.

[\[DOWNLOAD NOW \]](#)

It only takes up about 200K on your hard disk. Also, you will not have to connect to the internet to use it.

Otherwise, if you'd just like to try out the Eye Chart Generator on the web, [please proceed...](#)

- Read [Instructions](#).

PRESBYOPIA REDUCTION

By Ray Gottlieb, O.D., Ph.D.

Presbyopia can be reversed or delayed by learning to cross your eyes while using the presbyopia reduction chart. I first used this approach in 1976 with a 52 year-old man with 20/200 near and 20/40 distant acuity. He had typical middle age sight, was slightly farsighted and had been wearing reading glasses and bifocals since age 40. After teaching him to relax his mind and eyes using the Bates palming, sunning and central fixation drills, I taught him converging (crossing his eyes) and diverging (uncrossing his eyes) exercises. I made a chart with a pair of identical targets separated horizontally by two inches. Two weeks later his acuity had cleared to 20/40 at near and 20/20 at 20 feet. How did he do it? He loved the converging exercise and practiced whenever he had a chance. He did it when he ate, in the bathroom, at bedtime and at work he would spin around in his executive swivel chair as he converged and diverged the targets. Did it last? Three years later, at age 56, his vision was even better.

I can read tiny print without strain. When I started to "need" reading glasses in my early forties, I practiced the same exercise and a few weeks later had clear vision at near with no strain. After many years I still see small print easily and don't use glasses for reading. I don't need to practice this daily or even weekly. After 3-4 months of neglect my vision blurs and my eyes feel strain at near. Usually I wait a few days hoping it will go away by itself but finally practice this exercise and after four or five days the problem goes away. I do fifteen minutes the first day and then on subsequent days exercise for fifteen minutes several times up to an hour's worth (four fifteen minute sessions throughout the day) on the last day. I follow the procedure described below making sure to relax to let the small print clear under dimmer light and at closer distances. Soon my focus returns and I don't exercise until I need it again few months later. I don't know if there is an upper age limit. Recently I was encouraged when a 75 year-old optometrist who has been wearing +2.50 D trifocals for 20 years practiced the exercise. After four months he could read the tiny print on the presbyopia chart with no Rx without converging. Other optometrists report similar results.

Many of my patients gain sharper vision and also feel better in their eyes. Some people learn to do this quickly and easily but others must struggle at first to overcome frustration and discomfort but eventually come to enjoy the exercise because it feels good. I recommend that they also do Bates' palming and sunning exercises to relax their eyes but not everyone does. And these exercises don't work for everyone even after dedicated practice. If they exercises are going to work, you should know within a month.

Not everyone can learn to do the exercise. Poor convergers have to first build convergence by looking at nearer and nearer targets and aiming their eyes back and forth between near and far targets. After this gets easier they can try the presbyopia exercise. Strabismics and people with more embedded binocular problems need supervised vision therapy.

If these exercises cause discomfort, limit the initial convergence workout time, do it several times a day but for very short periods sometimes just for 30-60 seconds. As convergence gets stronger and more comfortable, gradually increase practice time to fifteen minutes at a sitting. The eyes should be relaxed before starting, after finishing and any time the eyes feel strain.

Learning to use the presbyopia reduction chart.

Not everyone can voluntarily cross their eyes but those who can should do so with the chart held about 16 inches away. Be aware of the two black dots near the top of the page. They should double and you'll see three or four dots. The goal is to see three dots. So move the chart closer or farther and modify how much your eyes cross until you can see and hold three. Make sure the page is not tilted.

If voluntarily going cross-eyed is not possible, hold the chart about 16 inches away and place a pen with its tip just under the top pair of dots. Look at the pen point while slowly pulling it nose-ward. Notice the dots behind the pen. First they double into four but when the pen is about halfway to the page, the middle two dots merge together and three dots magically appear. This is a big thrill and in the excitement fixation on the pen is lost and the original two dots return. Practice seeing three dots by looking back at the pen. Look at the pen and not the dots. Become aware of when the pen doubles.

To gain strength, place the pen at this distance, see the three dots, and slowly move the pen and chart together a few inches to the right, then left, up, down. Try moving closer, farther or in a circle always seeing three dots. Practice while standing up, walking and sitting down. Learn to blink and breathe to reduce strain. Don't tip the target.

The next step is to see three after removing the pen by learning to see three while making brief and then slow blinks.

Can you feel your eye converge? See the middle dot try to hold three as you slowly move the pen toward your nose. At first the three dots stay briefly for just a second but with practice for longer. To strengthen the reflex, move the target left, right etc., as described before. Soon converge will come easy with no pen required.

Now look at the words in the paragraph around the middle dot. Look at the big letters in the word "Cross" and then at smaller print. If this is difficult, use the pen for support. Relax to read the small print. Near vision should be significantly clearer while converging. With continued practice it will get even clearer and you should notice improvement in your every-day near vision.

Change brightness, nearness and text size.

Bright light increases clarity. To improve near acuity, start in high brightness. As the letters clear, reduce the light to learn to relax and clear them in dim or even in candlelight. If so, even smaller print will be clear under bright light. Repeat the process: Find the threshold of clear vision under ideal lighting, relax and then clear in less light. Use the same technique holding the chart at different distances. Clear large letters at sixteen then fourteen, twelve, ten or even six inches away. At each distance relax and let the print clear. With success, move back to sixteen inches and do the same with smaller text size. Repeat for smaller letters. Stay just at the threshold for seeing clearly, go into slight blur, relax to clear (this may take several minutes), then slowly move toward more demanding conditions.

Learn to relax by following the directions in the bottom paragraph. Let the target focus without strain. Let convergence stimulate and strengthen accommodation so that focus eventually clears at the near reading distance without glasses and without converging.

The paragraphs are positioned on the page to appear in 3-D. Converging two adjacent paragraphs makes just the middle one sink behind the others. Diverging produces the opposite: the center paragraph floats between you and the page.

Diverging the charts

Although the text in the presbyopia chart mentions only convergence, divergence is also important. Place the nose on the page below the top two dots so that one dot is before each eye. Pretend to look through the dots into the room beyond the page to see one big, blurry dot. Move the page slowly out and two more dots should appear on the left and right side of the central dot. Don't focus directly at the page but focus softly and be aware of the whole room. Learn to keep three dots while looking at the center one. If this method fails, copy the presbyopia chart on transparency. Look through this transparent chart at a plane wall one or two yards away. This will force the eyes to diverge beyond the page to see three dots. The next step is to look at the center dot without converging back to two dots. Try sliding a white piece of paper behind the transparent chart. It helps to look for the 3D effect. Diverging makes middle paragraph to appear to float closer, above the page. Practice moving the target and walking as described above. Work to diverge the targets and see the print clearly. If you can see the small print while diverging the chart, you are no longer a presbyope.

Some people over-converge (esophoria) and can't diverge easily. They compulsively try too hard and instead of letting convergence relax they unconsciously converge more. Lenses and prisms and more extensive vision training may be necessary. Myopes usually do better at divergence without glasses.

Diverge and converge the chart during each session. Practice the difficult way until it becomes easy. Practice with and without glasses. Teach yourself to alternate, diverging and converging the targets quickly and with clear vision. This stretches accommodation and convergence ranges even more.

Blink and breathe.

Cross your eyes to clear this print. Hold a pen, point up, half-way to this page. Look at the point. Notice the dots above. See four? Move the pen nearer or farther to see three. To learn to hold three dots without a pen, look at the middle dot and bring the pen slowly to your nose. Is this clearer with crossed eyes?

Cross your eyes to clear this print. Hold a pen, point up, half-way to this page. Look at the point. Notice the dots above. See four? Move the pen nearer or farther to see three. If you cannot read this fine print, do not strain. The more you strain the worse you'll see. The secret to better vision is relaxation. Excess tension in eye muscles stops circulation and makes vision inflexible and insensitive. To clear this print, cross (converge) your eyes as above. Can you see the print through either dot while converging? Can you read it?

You can overlap these eight paragraphs seven ways by converging at different distances. Hold your pen closer to converge more or further to converge less. Do you have to converge more to clear this print? Notice the depth in the center paragraphs as you change convergence. Breathe!

Relax while clearing this tiny print. Learn to wait for the letters to clear. If you see blurred images, ghost letters or black or white lines, do nothing. Allow the image to change by itself. Don't strain for clarity. Breathe, blink and practice letting go in your feet, legs, pelvis, stomach, hands, shoulders, neck, jaw, and eyes. Breathing should not be forced. Try rapid and slow blinking. This new way to focus will become stronger and more automatic. Eventually you will see clearly without converging.

STRING OF PEARLS CHARTS

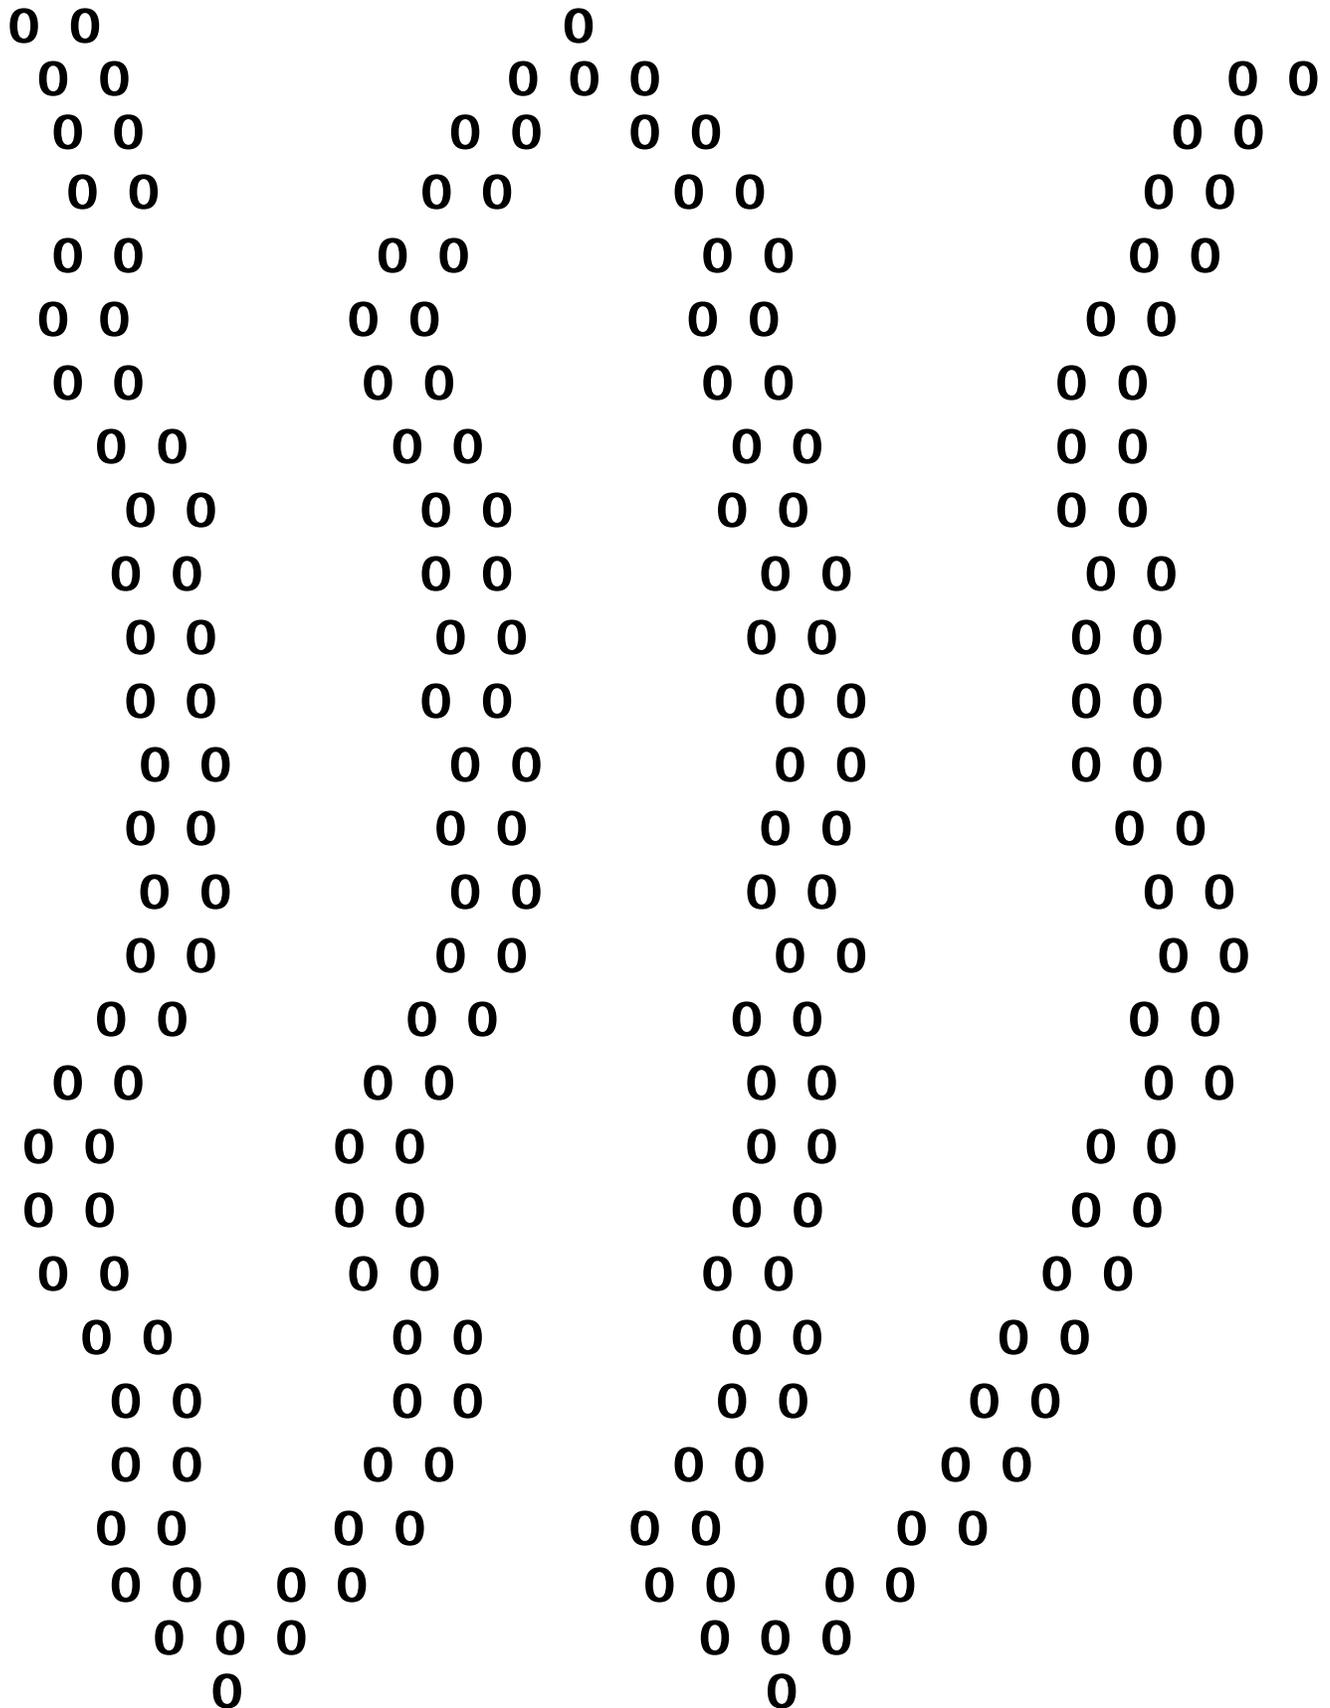

Advanced fusion training procedure to be done after mastering the larger convergence charts.

- Purpose:** To develop fine convergence/divergence control and 3D awareness.
- Equipment:** String of Pearls Convergence charts starting with the largest.
- Set up:**
1. Hold the chart at normal reading distance parallel with your face.
 2. Keep it level.
 3. Don't strain. Keep breathing and blinking.
 4. Practice with and without wearing your glasses if possible.
- Convergence:**
1. Look at the top left pair of circles. Converge to make three. This is tricky, and requires relaxation and fine control. Look at a small target (needle or unfolded paper clip) near the page just below the O's.
 2. Depth awareness is the secret to holding small amounts of convergence. The center circle should float towards you. Hold a pen or pin near the page to increase the 3D illusion.
 3. Follow the string of pearls, slowly, moving one-by-one along its whole length. Count the pearls as you go. Be aware of depth as you move from point to point. Spread your stereo awareness to see a raised line of circles down the middle. Move your eyes in a steady flow from the beginning to the end of the string. If you lose convergence, start again at the beginning.
 7. When you succeed, speed up, following the raised string of pearls.
 8. Practice closing and opening your eyes or looking away and back. Try to regain fusion and the 3D illusion as quickly as possible.
 9. Move the chart closer & farther, up & down, in a circle, Can you walk around the room while following the raised string of pearls?
- Divergence:**
1. Diverge to make three O's by looking slightly beyond the page. Make a transparent xerox and practice looking at a small target an inch or less beyond.
 2. See the depth -- the middle circle should project away, as if behind the page. Depth awareness is the secret to holding small amounts of divergence.
 3. Repeat steps 3-9 while diverging.
- Advanced Procedures:**
1. Repeat the whole procedure with the smaller String of Pearls charts.
 2. Repeat alternately diverging and converging each pair of O's along the string.
- Keys to Improvement:**
1. When you see three and hold the tiny amount of convergence or divergence.
 2. When you can see 3D.
 3. Increasing awareness to see 3D along the length of the whole string.
 4. Moving your eyes along the pearls until you succeed all the way.
 5. When you can blink, breathe, and succeed without effort and feel your eyes, body and mind relax.
 6. When you can move the page and walk around without losing the illusion.
 7. When you can succeed at even the smallest separations.

Legal Notice

If you have serious problems with your eyesight, please seek the advice of a qualified eye care professional.

This work is released into the public domain. This document was originally designed by Joel Schneider in May, 2002.

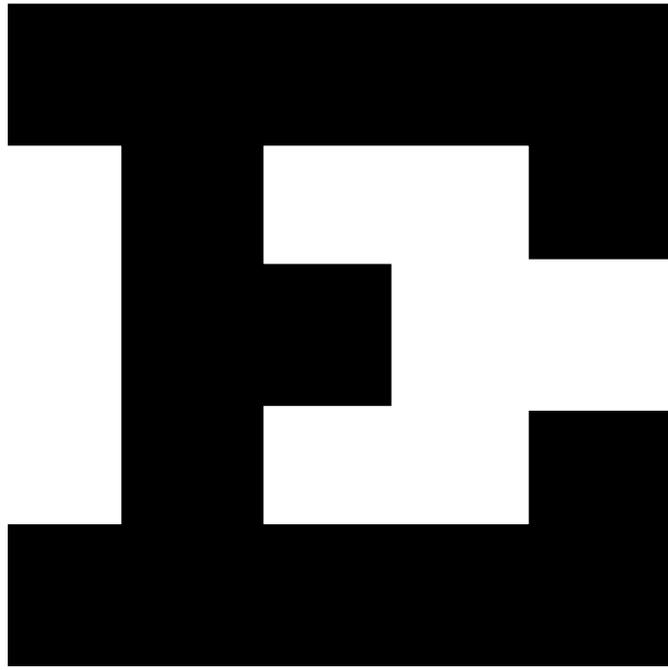

Technical Notes

The document is laid out to be printable on either letter-sized or A4 paper. Distance values for normal eyesight are marked in both U.S. Customary and metric units.

When printing the PDF version of this document, be sure to disable the "Fit to Page" print option.

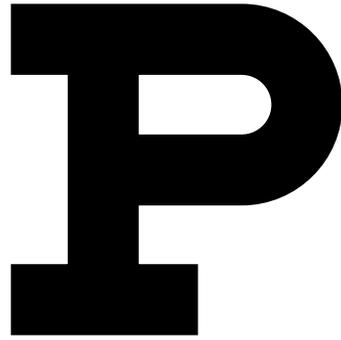

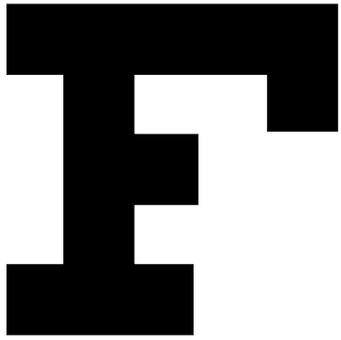

To quickly test whether the eye chart is printed at the correct size, measure the height of the big letter E. It should be 3.49 inches (88.7 millimeters) high. This height represents 5 minutes of subtended arc at a distance of 200 feet (60.96 meters).

Astigmatic Mirror

by *Vic Cinc*, Sydney, Australia.

For your very own astigmatic mirror, you may [download the above color image](#), or [make your own](#).

So now you have a picture of what looks like the iris of the eye. Place it on a window at eye height, and get back far enough so you can still make out most of the lines with your glasses/contacts off.

Okay. Look at the lines near the center. What do you notice? If you are astigmatic you will notice that some of the lines are darker in some directions than others. Get used to the wheel for a little while and experiment with it. Try tilting your head or looking at it sideways. Try looking around the inner or outer circle. Try just staring blankly past the wheel. Notice what happens in each case. Try blinking or yawning. Try palming for a minute or two. Try covering each eye with a hand quickly to see what the difference is between your eyes.

If you a "typical" astigmatic, you may see the lines near the horizontal are clearer and darker than the lines vertically. You may also find the lines near the horizontal are spaced further apart and the vertical spaced closer together. You might also find the inner circle in not quite round.

Try looking at it with your glasses on. If your glasses fully correct astigmatism, then *all* the lines should be the same darkness and distance apart. If your glasses do not correct the astigmatism properly than you will still see some lines darker than others.

Using the Astigmatic Mirror to Reduce Astigmatism

The astigmatic mirror gives you a direct and accurate record of your condition. You can use it as a direct feedback device, a mirror in which any changes you can make and learn to make will be instantly displayed.

Say you find the lines that are horizontal to be darker. Your aim is to make the vertical lines darker. So begin by removing any glasses/contacts, relaxing and taking a few deep breaths. Blinking naturally and breathing normally, find the line which is the faintest, and move your eye slowly and deliberately up and down that line, imagining it to be getting darker and darker. Tell your self to relax, relax. And imagine that line to be getting darker and darker. The key is to *relax* your eye has much as you can. You may want to start by massaging around the eye, and maybe doing a couple of minutes of palming. With a bit of practice you will be able to make the lines in any orientation darker than the rest, but your goal is to make them *all* equally dark. If you are myopic its worthwhile to place your wheel on a window, as you get a lot of contrast between the black and fluoro colours of your wheel, and also you can check out the window to see what effect playing with the wheel is having on your vision. Its also *very* worthwhile putting one up at work and at home and whenever you get a break you can play with it and see what

happens. The astigmatic mirror allows you to leverage your own visual distortion to work for your benefit.

How to draw your Astigmatic Mirror

Drawing the Wheel

For the wheel, you may use our [PostScript](#), [PDF](#), or [GIF](#) black-and-white templates, or follow these instructions:

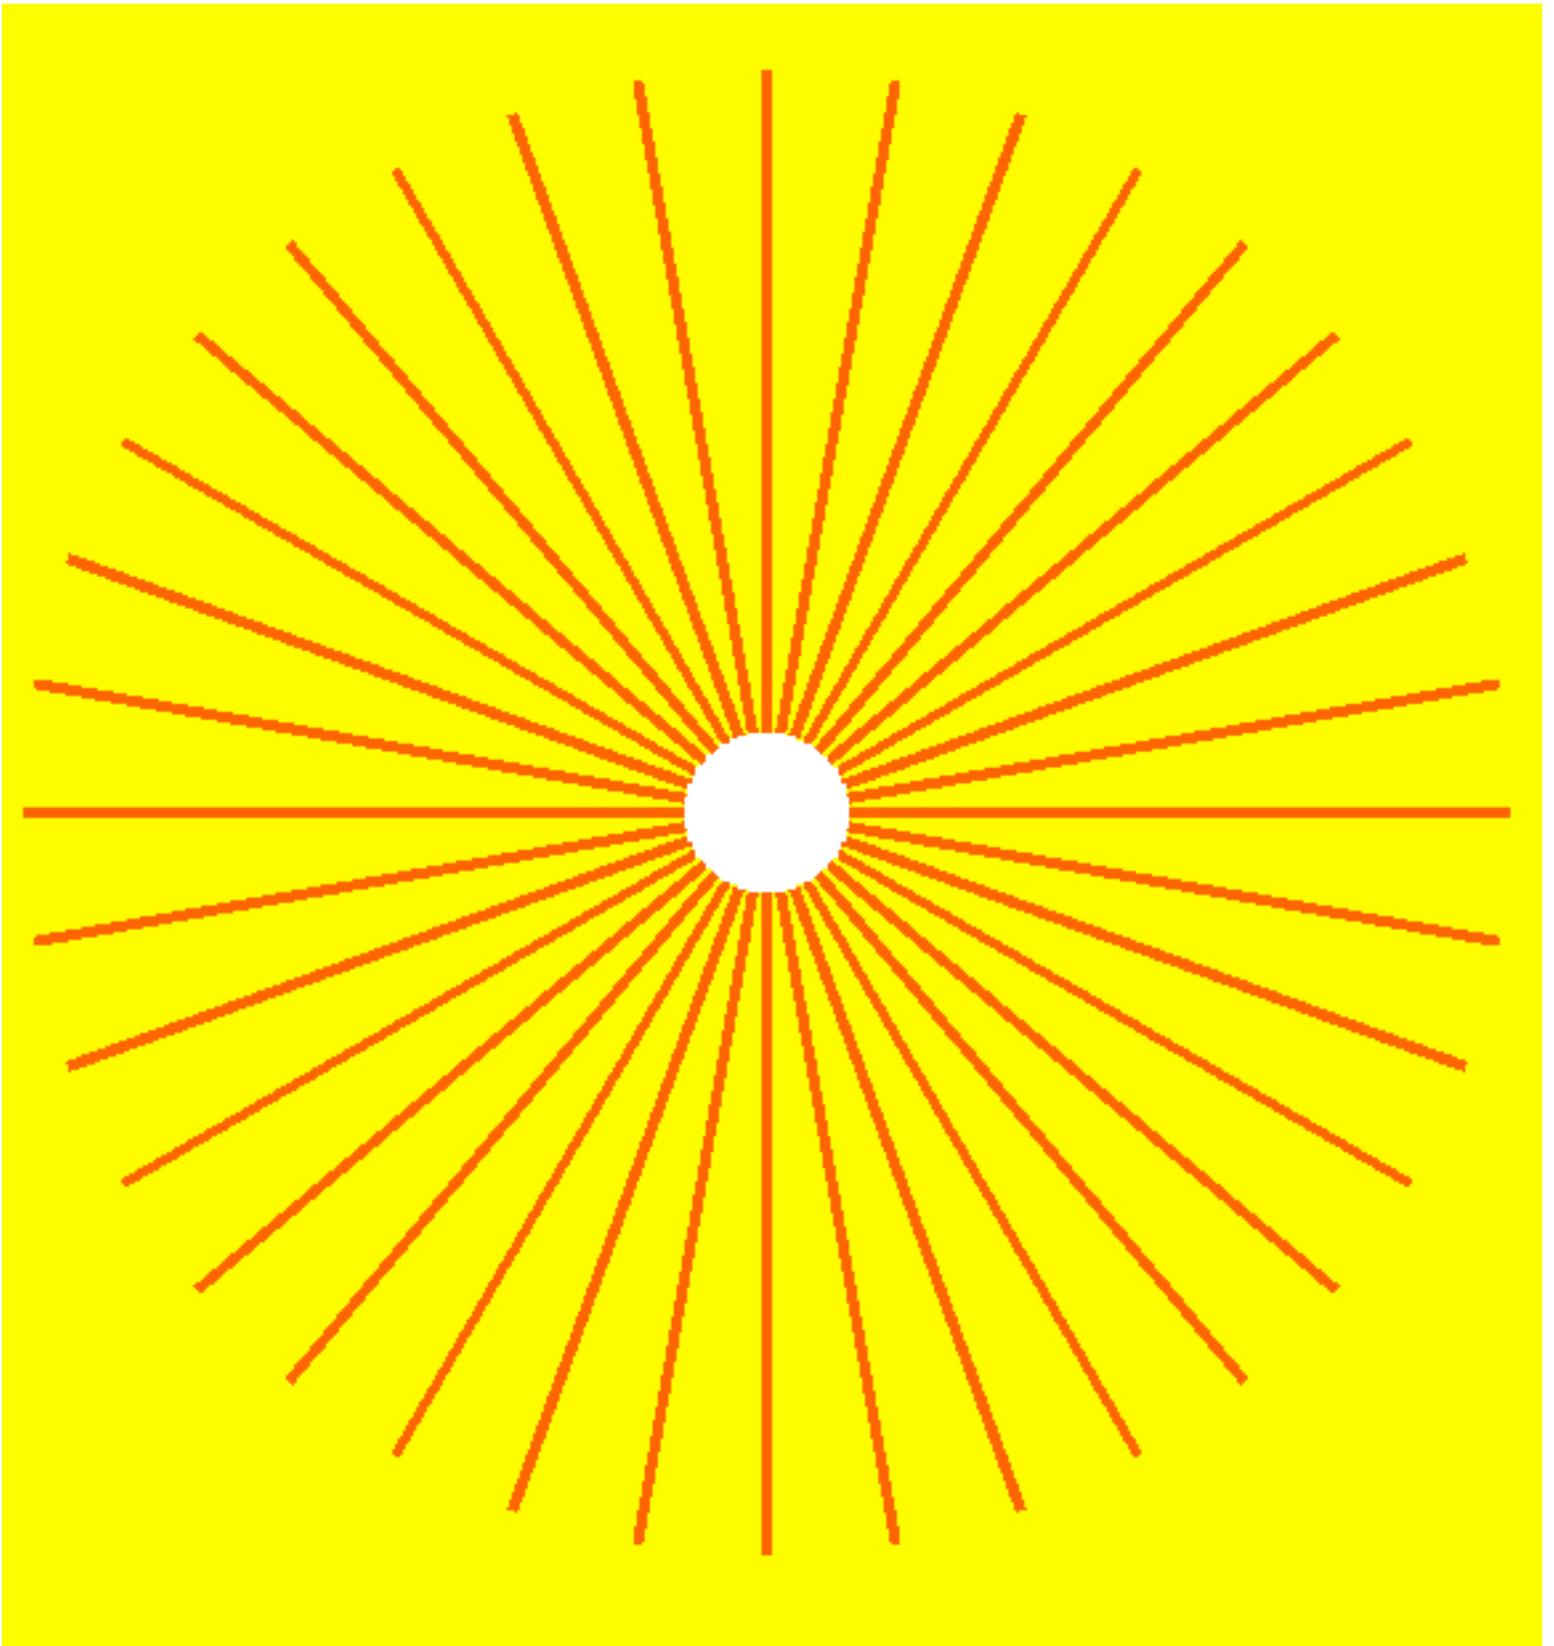

You will need an A4 sheet of paper, a ruler, a protractor, a compass, a pencil and a 0.2mm black marker. Find the center of the paper, and using a pencil draw a circle almost as large as the paper (diameter 20cm) with the center of the circle at the center of the paper. draw another smaller circle from the same central point about radius 1cm. Then draw a line cutting the large circle in two, but not crossing over the inner small circle, ie, Leave the inner small circle blank. Then divide the two pies you have in two again. Again not drawing inside the inner circle. Now you have 4 pie shapes. Then divide each of these in two again, so you have eight wedges, and then again so you have 16 and then one final time. So you have a spoke every 10 degrees. The result looks like a bicycle wheel. Now using your marker draw over the spokes of the wheel with nice sharp dark black lines, make sure all the lines are the same darkness.

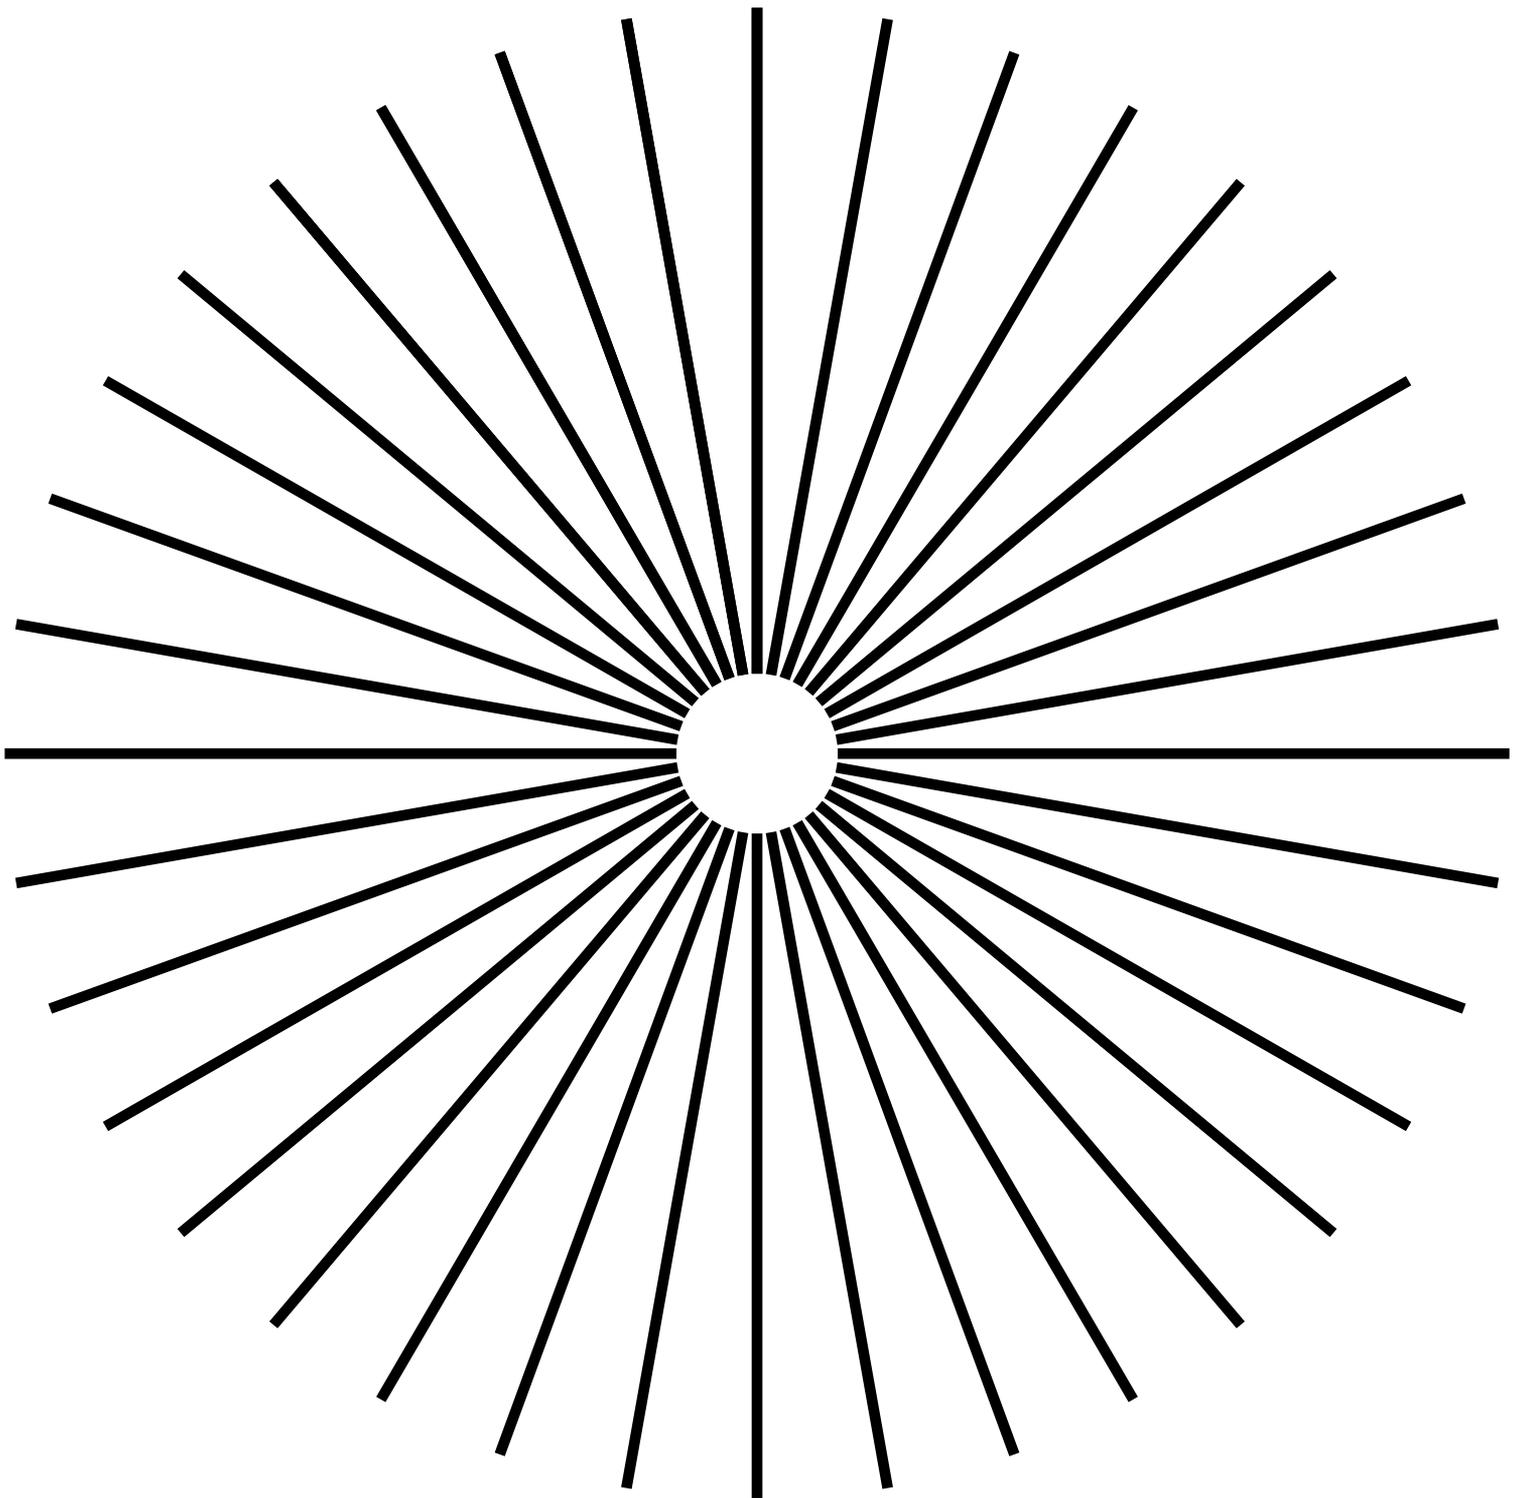

Coloring it in

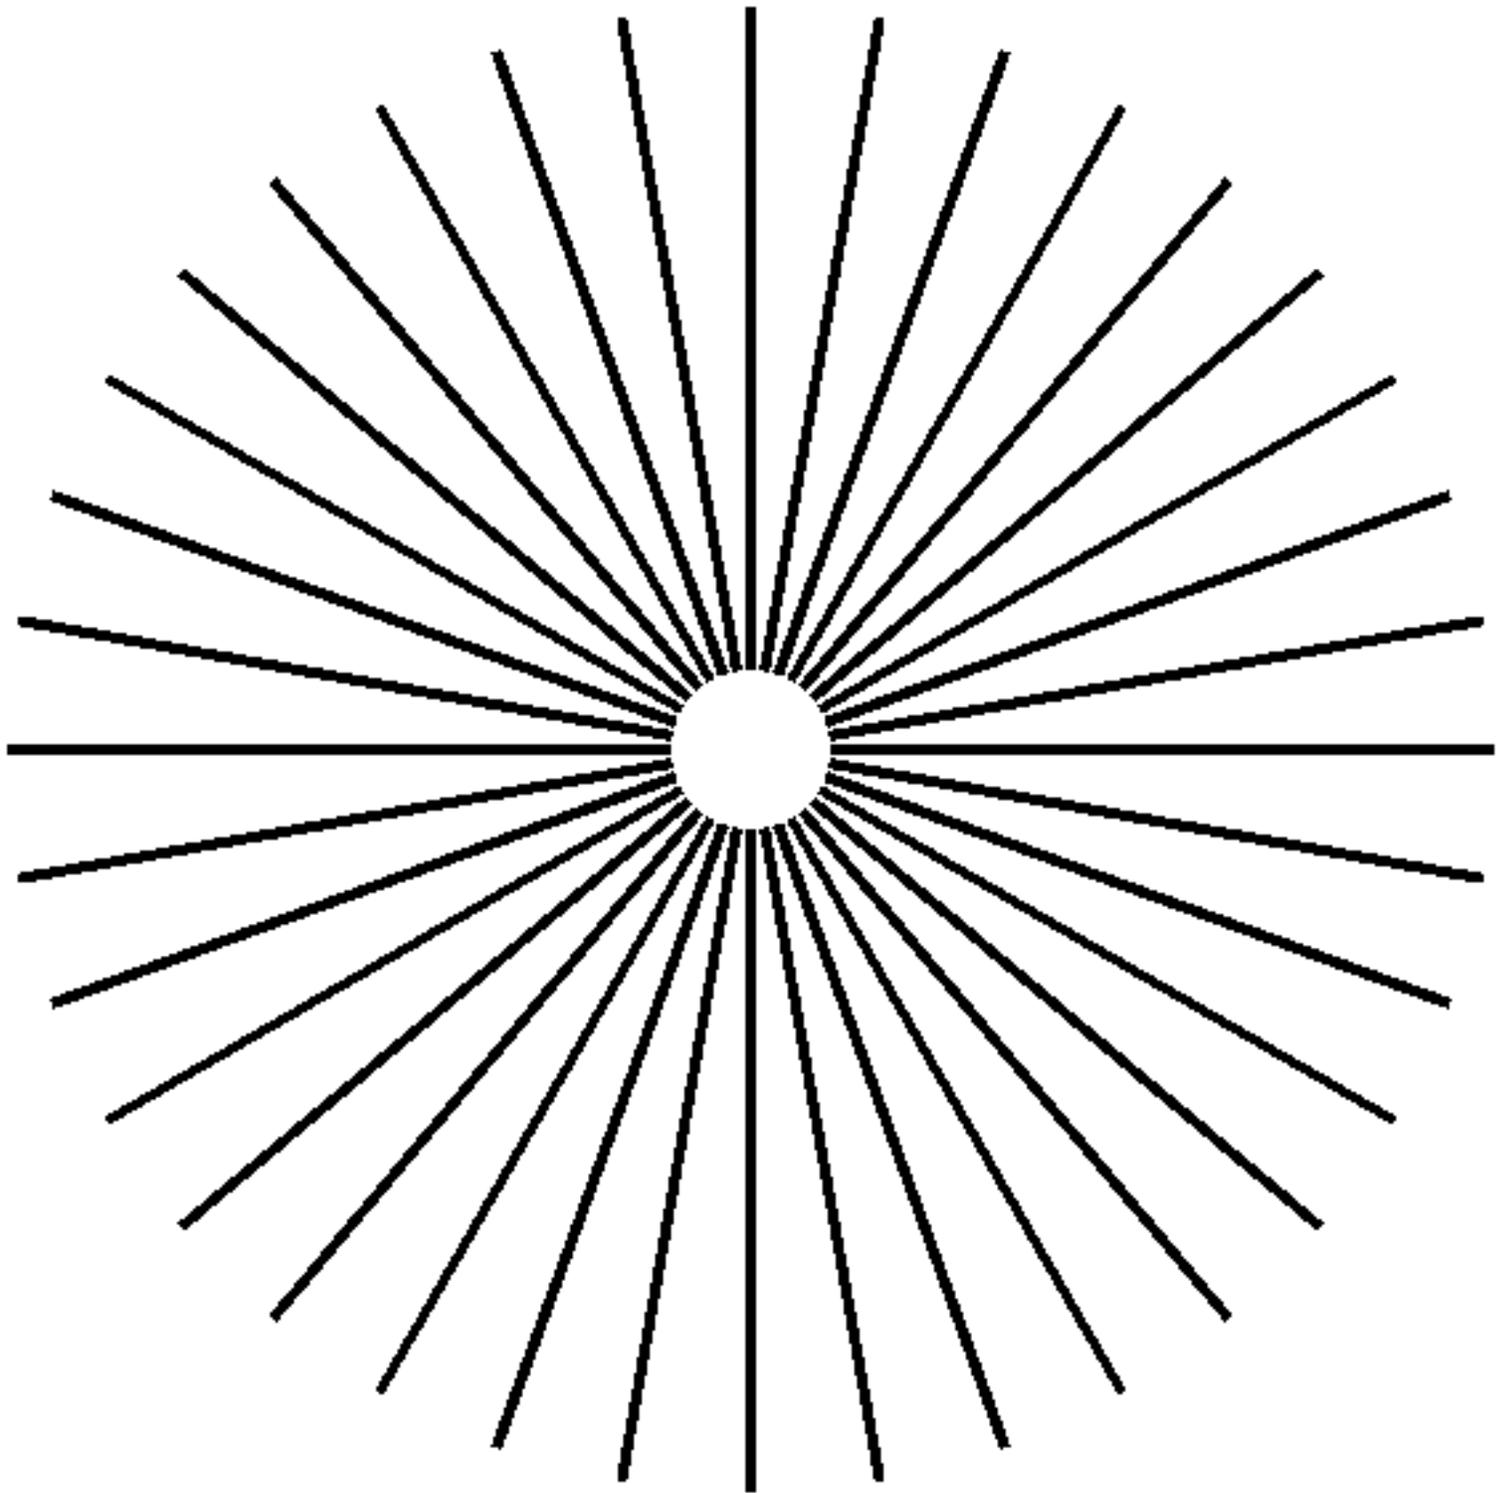

Now you have your black on white wheel. Use a bright yellow and bright orange fluoro highlighter. The colors aren't important and you can even just leave it black and white. Outline each spoke of the wheel with the orange highlighter and fill in the gaps between spokes with yellow. Leave the inner circle white. Later you can experiment and choose colors that pleases you. The bright colors are useful because they attract the mind and stimulate all the visual meridians.

The Case for the Preventability of Myopia

by *Alexander Eulenberg*, Bloomington, Indiana

Last Revision: March 3, 1996

Thanks to the Indiana University Optometry library and Professor David Goss, for assisting me in finding various information pertaining to the subject. The author is of course wholly responsible for the content of this paper. --AE

Introduction

Persons with myopia, or nearsightedness -- those whose eyes are unable to see distant objects clearly -- are usually prescribed concave lenses to compensate for their defect and allow them to see clearly. Although such lenses are incapable of relieving the underlying condition, the present treatment is felt to be justified because it relieves the most obvious symptom. In spite of this "treatment" however, the condition usually worsens for a number of years, resulting in poorer and poorer vision without glasses, and the necessity for stronger and stronger lenses to provide normal vision. As far as the public is told, the only hope for myopes is the possibility of slowing its progression through special bifocals or contact lenses, or to cure it through surgery. Never is there mention of the possibility that myopia can be prevented or cured by any means short of surgery. In this paper I will review the history of research on the nature and proposed treatments of myopia, with particular attention given to the much-neglected case for the preventability and, to some extent, the reversibility of myopia.

The Nature and Prevalence of Myopia

Myopia may be defined as the state where an eye's refraction is too strong to converge rays from points from distant objects to a point on the retina. That is, distant objects always end up focused on some point in front of the retina, causing an indistinct image. Myopia is often compounded with astigmatism, which means that the error of refraction is increased or decreased along one meridian of the refracting surface, usually the cornea, but sometimes also the lens.

Newborns vary greatly as to how far they are able to focus (Cook & Glasscock 1951), but by the age of five years, the overwhelming majority of children have developed normal or slightly farsighted refraction (Kempf et al. 1928, Mohindra & Held 1981). It is during childhood and adolescence that most myopia begins to appear. In the United States, it is estimated that between 15 and 25 percent of the adult population is myopic, most of whom had normal refraction before the age of seven years (National Research Council 1979:3-4). Among academic populations around the world, including military academies, the proportion of myopes often exceeds 50%. (p. 20)

It is generally recognized that myopia can be functional as well as structural.

Functional myopia is an inability to see at the distance stemming from a dysfunction in the muscles (ciliary) that regulate the medium of accommodation (crystalline lens). In other words, the eye is in a contracted state, perpetually focusing for near objects. This type of myopia is cured if the ciliary muscle can be made to relax long enough for the lens to regain its previous state. It has been the practice to call the type of myopia due to an overcontracted focusing muscle "pseudomyopia."

As for structural myopia, it has long been observed that myopic eyes measure on average longer than normal eyes, and thus the cause of myopia is generally agreed to be "long eyes"; the rays from distant objects being prevented from converging on the retina because the retina is too far back. A indirect measure of the lengthening of the eye in myopia can be made by reference to the evidence of expansion at the back of the eye, which is visible with an ophthalmoscope. Other evidence of a lengthened eyeball is visible to the careful observer. In an early textbook (Wells 1883), it is noted that in myopia of considerable degree, "the increase in the length of the eyeball ... can be easily recognized when the eye is turned far inwards towards the nose." Sato (1957) writes that the connection between long eyes and myopia was made as early as 1632 by examination of a surgically removed eye, and that the relation between long-eyedness and myopia was, according to the German ophthalmologist Carl von Hess, well-known to doctors in the 18th century. By the end of the 19th century, the idea that myopia is caused by an increase in the length of the eye had been established as fact. J. S. Wells writes in his textbook (1883) "The most frequent cause of myopia is an abnormal increase in the length of the eyeball in its antero-posterior axis."

However, there have been opponents to the idea that structural myopia is acquired by an increase in the length of the eyeball. Tikasi Sato (1957) made a valiant attempt to prove that the association between lengthened eyes and myopia was not at all causal, and that advances in myopia were entirely due to adaptive organic changes in the lens and ciliary muscles, producing a too-powerful lens. At the time, the only data on axial length was from corpses and lensless patients, as ultrasound measurement techniques were not available to him. Based on a statistical analysis of his cross-sectional data, he concluded that acquired myopia could be explained entirely as an increase in lens power. However, more recent longitudinal studies using ultrasound have confirmed (e.g. Tokoro & Suzuki 1968, Goss et al. 1990, Grosvenor & Scott 1993, Zadnik 1994) that of all the ocular components of refraction, an increase in axial length is most responsible for increases in myopic refraction, for children as well as young adults, regardless of degree of myopia.

For theoretical purposes, it is convenient to talk of "true axial-length" versus "functional" myopia, but in practice, there is no easy way to distinguish the two types. True, atropine and other chemicals known as cycloplegics have been used to paralyze the ciliary muscle and thus eliminate the "pseudomyopia" effect, but as optometrists have often pointed out, paralysis of the ciliary does not completely relax the muscle, and in fact, sometimes "after the use of a strong solution of atropine, minus lenses were prescribed by the oculist, when upon reexamination without a mydriatic it was found that plus [farsighted] lenses were required" (Raphaelson 1911). Optometrist Eugene Heard notes (1914) "an increasing number of cases coming to us, having failed to get relief from oculists who had put them under these various cycloplegics, the cramp not being revealed by their method, as it was not relaxed, but locked up." And while cycloplegia is very likely to reveal latent hypermetropia, in nonmyopes, more recent studies (Rengstorff 1966, Ludlam et al. 1972) have confirmed that the effect of a cycloplegic on manifestly myopic eyes, especially in a clinical setting, is often unpredictable, and that refractions done on drugged eyes are as likely to reveal more myopia as less, compared to the refraction performed without cycloplegia.

Cause of Functional Myopia

Close work theory

Functional myopia is usually held to be caused by excessive close use of the eyes. It is supposed by many to be only temporary and not to require treatment. Early investigators, however, observed a tendency for functional myopia to become more or less permanent. Chalmers Prentice, a physician writing in 1895, explained how excessive near work leads to the inability to see in the distance:

All evidence bears out the fact that myopes generally are people of a higher civilization, who exercise their eyes at the near point, and thus establish an abnormal impulse in the ciliary centers during such use of the eyes. The stimulus has been so constant for a long period that the impulse to the ciliary is unable to suspend itself and bring about distant vision again. The motive-impulse keeps coming. The ciliary will not relax from its contracted condition, the refraction remains high, and the patient near-sighted.

Optometrist O.J. Melvin observed:

Usually [patients] express [the onset of nearsightedness] in these terms: "After doing a lot of close-work, I find that I have to focus my eyes for a little while before I can see clearly at a distance." These patients report that this period of "re-focussing" took longer and longer until finally they saw dimly at a distance all the time. (Melvin 1936)

That over-use of the eyes at a very close range can bring on functional myopia is hardly questioned today, although modern articles tend to downplay its significance. Ciuffreda & Ordonez (1995) characterize the myopia that follows from sustained near work as something that occurs in "some patients" that lasts "several seconds or even minutes".

Mental strain theory

A different opinion on the cause of functional myopia is given by William Bates (1912). First of all, he proposed that functional myopia was produced not as an after-effect of having viewed near objects, but by "an effort, usually unconscious, to see distant objects" which became habit. Using the retinoscope, Bates observed people with normal vision as they looked at "new, strange, or unfamiliar" objects, such as an unfamiliar eye chart, map, or strange handwriting on the chalkboard. He found that whenever an unsuccessful effort was made to recognize these objects (as evidenced by squinting, frowning and other contortions of the eye and face) various types of myopic refraction were produced: "myopic astigmatism, usually--compound myopic astigmatism, occasionally, or simple myopia infrequently." This temporary myopia or myopic astigmatism could be avoided, Bates found, if the person relaxed while viewing distant objects. Another difference in Bates's understanding of functional myopia was that he defined it as being produced by muscular action -- any muscular action -- not just the commonly accepted regular focusing action of the ciliary muscle on the lens. He observed functional myopia in "cases in which the accommodation is apparently paralyzed by atropine, and in aphakia after cataract extraction."

Modern support for Bates's mental strain theory of the production of functional myopia comes, among others, from the research of Bullimore & Gilmartin (1987). They have measured the resting state of accommodation before and after tasks requiring various levels of "cognitive demand" such as solving arithmetic problems. They found that tasks involving relatively high levels of cognitive demand, independent of optical stimulus to focus for near, will cause the resting state of the focusing system to move towards near-focusing.

Very little research has been done to test the idea that myopic astigmatism could be produced by the action of the

extraocular muscles. However, optometrist J.W. Parker (1931) reported that he was able to relieve many cases of astigmatism through extraocular muscle therapy (he did not specify what kind), and Fairmaid (1959) reported that significant corneal changes occur whenever the eyes are pulled together to converge.

Compromise theory?

It should be noted that the two proposed causes of functional myopia -- protracted near work and a habitual strain produced when looking at distant objects -- are not incompatible. In fact, Bates himself hints at a connection in an early paper (1911):

Why did children strain their eyes when looking at distant objects? They strained because their experience had taught them that to accomplish most things an effort was required. They learned that they saw near objects more distinctly by making a voluntary effort. Naturally, most of them strained, when looking at distant objects, to improve their sight.

Cause of Structural Myopia

What causes myopia of the structural, supposedly incurable variety? Throughout history, there have been three main explanations: the heredity theory, the close-work theory, and the nutrition theory.

Heredity theory

First, the heredity theory. This is the theory most widely accepted today. As mentioned previously, most children are slightly farsighted by age five or six; that is, they have more than enough capacity to adjust their eyes for focus on distant objects. But many of them lose at least some of their hyperopia as they grow. During this time, the back part of the eyeball lengthens. Thus, it is easy to conceive of myopia as simply an overshooting of the target of growth for the eye, a process determined completely by genetic factors. A modern textbook on refraction advises:

It is wise to explain to the parents that the glasses will have to be made stronger as the child grows bigger, because the eye also grows, and this progression of the myopia should not be a cause of undue concern. [Elkington & Frank 1991:181]

In other words, the commonly accepted and propagated opinion nowadays is that structural myopia is nothing more than the genetically preprogrammed overgrowth of the eye.

The hereditary explanation, the classic exposition of which was presented by Adolf Steiger in 1913, is based largely on the observation that there seem to be myopic and non-myopic "peoples", the ones with the longer literary traditions, such as the Chinese and Jews, having a greater percent of their populations being myopic than others. (Modern statistical support for this age-old observation is provided by National Research Council 1989). Steiger explains the correlation thus:

In the circles of scholars, etc., who are engaged in near work, myopia is not so much an obstacle to their profession. Consequently, myopic people tend to collect in near-work circles. When this state of things continues for many generations, by a natural selection, myopic people increase in near-work circles, which results in a special increase in the predisposition for myopia in near-work circles.

(Quoted in Sato 1957, pp. 29-30)

Since Steiger, genetics, or "relaxed natural selection" (Post 1962) has been held to be responsible for myopia in populations where near work is highly valuable. In primarily illiterate populations, such as Africans in Gabon (Holm 1937), or full-blooded East Greenland Eskimoes (Skeller 1954), myopia was found to be practically nonexistent. The explanation could easily be found in the supposed survival value of good distant vision in these cultures.

Modern studies have tried to isolate genetic factors, and for the most part, the authors conclude that there is a significant genetic determining factor for myopia. Teikari et al. (1991) did a study on myopia in fraternal versus identical twins aged 30-31, and found that doctors' myopic spectacle prescriptions for identical twins differ between the twins less than they do between fraternal twins. Zadnik et al. (1994), controlling for grade in school and amount of "diopter-hours" (hours watching TV + 2 x hours playing video games + 3 x hours reading) found that the eyes of nonmyopic children (ages 6-14) with two myopic parents tend to have less hyperopia (ie. are further along the way to myopia) than those with one or no myopic parents.

One problem with these studies, however, is that they are incapable of determining whether the correlations in amount of myopia are directly due to a shared genetic defect, or due to "myopia-risk-increasing" habits encouraged by myopic parents or lookalike siblings. [\[note\]](#) In any event, that there often are significant differences between twins' prescriptions (Teikari et al 1991) does show that genetics does not determine everything.

Several studies have shown that for at least one population, the natives of the Arctic region, myopia does not come from the parents. Francis Young et al. (1969) made a study in Barrow, Alaska, of 283 Eskimo children (6 to 25 years) and 225 adults (26 to 88 years). The sample contained family groups of parents and grandparents. The children had all gone to school, while the parents had lived a traditional Eskimo life. While less than 2% of the parents were myopic, approximately 58% of the children were myopic, and the severity of the myopia increased with number of years in school. There was no significant correlation between the parents' refraction and the refraction of the children. Since the percentage of myopes is very high, and the population sample had been all volunteers, it seemed possible that "in the younger volunteers, at any rate, there was a strong element of self-selection: they came because they had visual trouble." (Sorsby 1970). To rule out this possibility, the refractive status all children at the local school -- from age 5 to 16 -- was tested. "The results obtained on the remainder of the school population agree with the results obtained on the volunteer subjects." (Young 1970). In addition to Young's experiment, other independent surveys have been done, confirming beyond a doubt that throughout the North American Arctic, the children of the natives, brought up according to the ways of the white man, are far more likely to develop myopia than their parents were (Cass 1966; Morgan et al. 1973; Alsbirk 1979).

To summarize then, the hereditary theory, while plausible and very widely accepted, accounts for only very general tendencies, and is insufficient to explain the variations that do occur in people born with the same genetic material.

Close work theory

That close workers tend to be myopic, while the opposite is true of those who use their eyes to see things at great distances, is simply common wisdom. Tscherning (1883) did a survey of vision among people of various occupations. Confirming the widely-observed correlation, he found that the occupations that demanded more close work had a higher percentage of myopes than did the occupations that demanded less close work. Today, that a large proportion of cadets enter military academies with perfect vision but become nearsighted after four years of study, is a fact sadly acknowledged by military researchers (National Research Foundataion 1979:21-22). It is only common

sense to conclude that too much near vision causes the loss of far vision. An early proponent of this theory was Dr. Albrecht Haller, who, in his *Primae Linæ Physiologiae* (1758, S531), wrote that myopia was caused by an excessive amount of working with small objects at a close range. Writes David Hosack, MD, in the *Transactions of the Royal Society of London* (1794), arguing that such effects are due to the fact that the extraocular muscles change the shape of the eye when it adjusts to different distances:

Again, does not the habit of long sight so remarkable in sailors and sportsmen, who are as much accustomed to view objects at a great distance, and that of short sight, as of watchmakers, seal-cutters, &c. admit of an easy solution on this principle?

Before Helmholtz's (1855) theory of accommodation took hold (that only the inside of the eye -- lens and ciliary muscles -- change during accommodation), no further explanation was thought necessary. The myopic eye had simply twisted itself more or less permanently into a strong focus. Later, those who adhered to the close-work theory, Helmholtz's (1855) theory of accommodation, and the idea that myopia is caused by an elongation of the eyeball, needed to come up with a more complex explanation.

J. Soelberg Wells (1886) identified congestion of the inner tunics of the eyeball as the main cause of myopia. This could be brought about by "continuous use of the eyes at near objects," wherein

the near approach of the object necessitates a strong convergence of the visual lines, which causes an accumulation of blood in, and congestion of, the inner tunics of the eyeball, these conditions being increased still more by the stooping position generally indulged in during such employment. We can easily understand that this congestion and augmentation in the pressure of the ocular fluids must, if long continued, necessarily lead to an extension of the tunics at the posterior pole.

In 1895, Chalmers Prentice writes that the excessive innervation used in close work for accommodating and convergence, takes its toll on the tissues of the eye.

Thus myopia is the result of a nervous disturbance which causes an associated disarrangement in the impulses of assimilation in various parts of the eye, especially in the sclerotic coat. This disturbance in the nutrition of the sclerotic and other parts, tending to soften them and lessen their mechanical support, together with the pressure of the rectus muscles, probably brings about that elongation of the eye that we find in axial myopia.

S.D. Risley (1897), an ophthalmologist who did an extensive review of schoolchildren in Philadelphia, found evidence that the development of even low degrees of myopia is a result of injury caused by the strain of near work, as opposed to normal growth (emphasis Risley's):

A careful study reveals, during the early history of these eyes, *a more or less tonic cramp in the accommodation, injected external tunics, and a great hyperaemia of the optic nerve, retina, and choroid*. The subjective symptoms, together with the intra-ocular hyperaemia, subside under rest, but recur when work is resumed. If the refraction is *myopic*, the degree of myopia steadily advances, and is attended with certain intra-ocular changes of an unquestionably pathological character, which also steadily advance with the increasing refraction. If the eyes are *hypermetropic*, they have been observed, in a large group of cases to be hereafter noted, to increase their refraction; but in each instance the increase was attended with advancing pathological conditions of the intra-ocular membranes of the same nature as those observed in the myopic eyes. (p. 359)

This quotation is of special interest, since it is often alleged nowadays that pathological changes are characteristic only of a special class of very high "malignant" myopia (National Research Council 1989:90). Also, Zadnik et al. (1994:1326) say that their study showed that eyes that were assumed to be genetically destined to become myopic during school become longer "before there is any evidence of myopia" -- but it is clear that "evidence of myopia" in their survey only means having a refractive error of more than -0.75 D (those with a myopic refractive error less than 0.75 D were classed as non-myopes!). Zadnik et al. did not include an examination of the tissues of the growing eyes.

Optometrist Francis King wrote (1912:395) that the ill and the young are particularly prone to developing myopia at the strain of close work:

Personally, I have met with a considerable number of cases unquestionably due to measles or scarlet fever--doubtless the affection developed because of too great an application in study, reading or close work about the time of convalescence. Hyperemia of the ocular tissues followed. A long resisting power was inevitable. The choroid and sclera at the posterior pole were stretched, and so the eyeball was elongated. The same prolonged and continuous study by precocious children, whose tissues are not yet hardened or mature, would bring about similar results.

Further evidence that myopia is not overgrowth of the eye but injury, comes from the records of W. F. Norris and Risley (emphasis Risley's),

Adding [my] seventeen cases to the eleven observed by Norris, we have twenty-eight examples in which the change of refraction was observed through a series of years, and the static refraction of each eye repeatedly demonstrated by the rigid employment of a strong mydriatic for many days. Since the publication of these cases I have seen a much larger number presenting similar histories. My own cases, without exception, passed from the hypermetropic ball over to near-sight through the turnstile of astigmatism. In all of them the observed changes of refraction were attended with pain and symptoms of external irritation,--e.g., blepharitis, conjunctival hyperaemia, increased lacrymation, undue sensitiveness to light, etc.,--while the ophthalmoscope revealed advancing pathological changes in the choroid. In no instance did the eyes, in passing from hypermetropia into myopia, become emmetropic at any stage of their progress. (p. 363)

Risley was of the opinion that an inherent tendency toward astigmatism was what caused the increase in refraction in those forced to do near work. It is the failing attempt to relieve astigmatism through accommodation that causes myopia, according to Risley:

The struggle to improve the sharpness of vision by accommodative effort causes undue strain upon each eye and disturbs also the the proper relation between accommodation and the binocular balance. The irritation and hyperaemia caused by these anomalous conditions, sooner or later, in a large number of individuals, set up the pathological states which lie at the foundation of progressive near-sight.... I am of the opinion that the congenital anomalies in the form of the eyeball are hereditary rather than the myopia itself or any tendency to myopia. (pp. 362-63)

Another researcher who found a link between the development of astigmatism and the development of myopia was Joseph Raphaelson. However, instead of saying that astigmatism caused myopia, he asserted that prolonged intensive near focusing during school years where young hyperopic eyes are "given no opportunity to relax and to

stretch" (1958, 63) causes both myopia and astigmatism. He summarizes a report by E.W. Adams, OD, to the Optometric Research Institute:

[Adams] reports ... that in the first and second grades very little astigmatism is found, but after these two beginning grades each successive grade up to about the sixth increases the percentage of astigmatism; after the sixth the percentage remains about the same.

Recall also that Bates (1912), using the retinoscope, observed myopic astigmatism produced in children as a direct result of their straining to see.

One very theory on how chronic close focusing ultimately leads to permanent structural myopia was proposed by British optometrist O.D. Rasmussen (1956). It is perhaps the most simple.

Failure of the crystalline [lens] to recover from its highly convexed state may create secondary tensions by pressure on the irides and thus the angle of the anterior chamber. Such pressures, by reducing the flow of lymph may in due course affect the whole eyeball and by swelling slightly, automacially separate the foci from the retina. (p. 85)

Modern research on animals leaves no room for doubt that the ultimate shape of the eye can be severely influenced by environmental factors, although most of it has been looking at changes in the shape of the eye as "axial length growth" and has not dealt with the issue of whether astigmatism also develops as a result of a near viewing environment, or whether the development astigmatism is an important factor in the development of myopia. A representative anthology of the modern work in this area has been collected in Ciba Foundation 1990. To summarize, axial length myopia can be consistently induced in laboratory animals by sewing the eyelids shut, by raising them in low-light conditions, or by restricting their visual input to near or virtually-near (through minus-diopter contact lenses) objects.

Other experiments are worthy of mention. Francis Young (1981) conducted a series of experiments. In these experiments, monkeys were restricted to close-viewing conditions, sitting within translucent hoods. The experimental monkeys, both young and mature, consistently developed significant degrees of myopia. His studies showed that a slight increase ($\sim +6\text{mm Hg}$) in vitreous chamber (area behind the lens) pressure occurs during accommodation, accompanied by an decrease in anterior chamber (in front of the lens) pressure. The higher the accommodation, the greater the change in pressure. Under the assumption that a slight increase in pressure in the vitreous chamber will, over time, cause it to elongate, Young proposed that "as myopia develops there may be a temporary change in the thickness of the lens which is followed within less than a year by an increase in the size of the vitreous chamber." In other words, chronic over-accommodation could bring about a change in vitreous chamber depth through its effect on the lens. The effect on the lens is temporary; the effect on the outer coats of the eye is permanent. Young found support for this hypothesis by comparing the measurements of lens power (phacometry) of subjects that did near work and developed myopia, to normal subjects. An increase lens power not found in emmetropes was determined to be responsible for the myopic shift that occurs subsequent to near work (in normal eyes, the lens decreases during maturation). Only later was there an increase in eyeball length in the myopes.

Wallman et al. (1995) showed that the choroid in chicks changes thickness, moving the retina forward or backward. When the chicks wore minus lenses, and thus their visual input was restricted to near viewing, their choroid thinned; when the lenses were removed, it thickened. Thus, even axial length may be affected by visual input, at least during growth periods. In fact, there is evidence that axial length responds to refraction throughout life; one study showed that adults who acquired myopia late in life after months or years doing near work in a textile factory evidenced

longer average axial lengths. (Simensen & Thorud 1994). More importantly, axial length appears to reduce to compensate for the lens's increase in power (Grosvenor 1987); it is possible that this mechanism could be accelerated in the face of a near-work reduced environment.

To summarize, early close-work theories, as well as Young's theory of myopia tended to treat myopia as a pathological phenomenon, while most modern close-work theories conceive of myopia as a matter of adaptive growth. Neither type of close work theory can explain everything about myopia, since different people growing up in the same close-work environment contract different amounts of -- or no -- myopia. If close-work induced myopia is pathological, then strength or health of the tissues of the eye may mitigate its effects. As noted by Risely, genetic factors influencing the shape of the eye may alter the intensity of the stress that close work entails. If, on the other hand, close-work induced myopia is a matter of adaptive growth, then differences in growth hormones, also genetically or perhaps nutritionally determined, may produce different reactions to the retinal stimulus.

Nutrition theory

Another possible factor in the etiology of structural myopia is nutrition. Emanuel Josephson (1939), a New York ophthalmologist, believed that the real cause of myopia is the "lengthening of the eyeball caused by increased volume of fluid in the eye," which had its roots in the adrenal cortex. To Josephson, the use of the eyes had nothing to do with whether or not they would become myopic. Rather, myopia was a result of a lack of salts in the body fluids, ultimately due to a malfunctioning of the adrenal cortex:

The adrenal cortex influences the water exchange of the body by causing retention of salt in the blood. The determining force in the exchange of water between the blood and the organs is their relative salt content. When the salt of the blood is reduced in quantity, water seeps, or osmoses, out of the blood into the organs. Insufficient secretion of the adrenal cortex causes such a disturbance and results in the increased flow of fluid into the eye. Thus is near-sightedness caused. (p. 26)

The way to prevent nearsightedness, Josephson argued, was to assure a properly functioning adrenal cortex. This could be done by assuring proper nutrition:

Malnutrition and defective diets play a large role in causing glandular disorders and the other disturbances which give rise to nearsightedness. A diet which is high in carbohydrates, starches and sugars, and low in proteins and fats, favors the development of near-sightedness. It is probable that such diets are apt to be deficient in vitamins; and that vitamin deficiency aggravates their effects. (p. 28)

He noted that the percent of schoolchildren with myopia rose and fell with the severity of the depression, and linked that to nutrition:

In 1925, it was reported that 25% of the schoolchildren attending a group of clinics in New York were afflicted with near-sightedness. With the advent of the depression, the figure rose steadily from over 40% in 1932 and to 72% in 1935. Reflecting re-employment and improved nutrition in 1936, the percentage incidence of near-sightedness dropped to about 51%. In 1937, the figure dropped to 42%.

P.A. Gardiner, a London ophthalmologist, also found a connection between poor nutrition and myopia. In particular, he found that myopic children are more likely to refuse to eat foods high in animal protein, this tendency being more

marked the more rapid the progression of myopia (1956).

Further support for the idea that myopia is caused by a lack of protein in the diet, comes from a remark by Elizabeth Cass, who examined the eyes of 2,124 Eskimo (1966), some of whom lived in a traditional village setting, and some of whom lived "in settlement or hostels, using White man's diet." (1966b).

Myopia is unknown among pure-blooded adult Eskimos. The majority have negligible refractive errors and a small number have low hypermetropia. Children whose parents have no refractive errors, after living on the white man's food for some years, develop myopia and carious teeth, i.e., they change from a high protein to a carbohydrate diet. (1966:1051)

Although it is possible to embrace the nutritional theory while rejecting the close work theory (Josephson [1939:22] writes "the theory ... that close use of the eyes determines the stretching of the eyeball and the development of near-sightedness is glaringly absurd from the physical point of view"), they are in fact compatible, if one grants the connection between near-seeing and general health, as observed by Prentice (1895, 1905) and McCormick (1906). The body's organs could be weakened by the poor blood supply caused by prolonged near-seeing. Raphaelson (1959:90), drawing on the work of these two physicians, notes:

Indirectly, prolonged near-seeing may affect the blood circulation by the excessive drain on the oxygen in the blood. When an excessive amount of nerve energy is used up by the visual centers, a likewise amount of oxygen in the blood which feeds the brain to create energy is used up. The loss of oxygen in the blood causes a derangement in the blood circulating system of our eyes and body.

In other words, proper nutrition depends on many things, one of which is a healthy nervous system. If close application of the eyes exhausts the nervous system, then not only is the blood in the immediate vicinity of the eyes affected, but also other organs may be affected, including the organs of digestion.

Treatment of Myopia--Optical Solutions

Concave lenses

The prevailing school of eye doctors has always held that myopia can only get worse, and the best thing to do is to prescribe concave lenses, to let the myope see clearly. In the beginning of the century, doctors claimed that myopia would get worse if the myope were not "fully corrected." For example, in 1906 (New York Medical Journal, Nov. 17, 1906) Dr. Wendell Weber commented that myopia would be diminished if the physicians were "careful to use full correction in young children." And even now, one finds comments in an ophthalmology textbook (Elkington & Frank 1991:181) such as "myopia of sufficient degree to prevent the child from seeing what is written on the blackboard should be corrected before the child starts formal schooling."

However, adherents of the close-work theory argue that myopia is caused and made worse by an excess of near focusing; thus, as minus diopter lenses intensify the dioptric demand on the eye, especially for near vision, they make myopia worse. They say that the gift of being able to see small words written on the chalkboard clearly at 20 feet during kindergarten is more than offset by the risk of floaters, flashes and retinal detachment, due to a severely elongated eye, at a later age.

Convex Lenses

While strict adherents to the genetic and nutritional theories of myopia see no harm and only good in the prescription of concave lenses, according to the close work theory, the opposite is recommended. Physician Chalmers Prentice (1895) advises the use of lenses which reduce the demand on the ciliary (convex lenses) for all study (p.151):

If the eyes are to be used at a distance of ten inches, aid them artificially by a ten inch magnifying glass; then the nerve-impulses to the ciliary muscle will be no more than if the patient were leading an outdoor life and viewing objects at twenty feet or more. The nerve-centers are not called upon for so excessive an impulse, and they become habituated to sending the same amount of nerve-force as if an outdoor life were led. ... If the little student at school or any other person using the eyes at the near point, were to be supplied with such glasses during the hours of study, on leaving the school room they could be taken off and the natural use of the eye at all other times would be quite sufficient to cultivate and establish the habit of accommodation.

Many clinicians in the past have used this technique for curing functional myopia. Usually it is for very low degrees. Writes ophthalmologist Walter Lancaster (1944):

A young man who had been wearing concave lenses asked if there was any way he could pass the test for 20/20 vision. Vision was 20/15 with glasses but was 20/30 without glasses. He was given a +1.00D. sphere for each eye to wear constantly for three days. His visual acuity was 20/15 without glasses and 20/15 with a +0.50 D sphere, and he read some letters of the 20/20 line with a +1.00 D sphere. Was his [structural] myopia cured? No, because he did not have [structural] myopia to begin with. He learned to relax his accommodation.

However, there have been reports of plus lenses being used to cure functional myopia of a significant degree. Physician Chalmers Prentice (1895:148-49) relates:

Age forty-three; myopia; had been wearing over the right eye -1.25 D, left eye -1 D, with little or no change for the space of two years; eyes in use more or less at the near point. I recommended the removal of the concave glasses for distant vision and prescribed +3.50D for reading, writing and other office work. After reading in these glasses for several days, the patient was able to read print twelve inches from the eyes. This patient was of more than ordinary intelligence and understood the aim of the effort. In six months I changed the glasses for reading and writing to a +4 D without seeing the patient. After using the +4 D glasses for several months he again came under my care for an examination, when the left eye gave twenty-twentieths of vision, while the right eye was very nearly the same, but the acuity was just perceptibly less. ... Similar results have been attained in thirty-four like cases; but the process is very tedious for the patients, and unless their understanding is clear on the subject, it is almost impossible to induce them to undergo the trial.

In younger patients, faster results have been reported seen with plus lenses. C. P. Rakusen (1937) did his work in Shanghai, China. He took ten children "whose age and history indicated recently acquired myopia." They all had a manifest refraction of one to two diopters of myopia. Their naked vision ranged from 20/100 to 20/200. He had the school physician verify the children's naked eye vision, after which he prescribed convex lenses, with base-in prisms, to be worn constantly for close work, and as much as possible for indoor activities. After only one week, every single child had improved naked-eye vision, and three of them had improved to 20/20. Rakusen followed the cases

for two years, and found that there was further improvement in all cases and no retrogression as long as the special lenses were worn for close work. The one child who discarded the glasses became nearsighted again.

Rakusen also cites a case of a girl who was prescribed concave lenses by an oculist who used cycloplegics. Rakusen had seen this girl for three years since the age of seven, who had been suffering headaches, but could read the distant eye chart with normal acuity. As she had a tendency to hold the book close to her face, Rakusen prescribed weak plus lenses, through which the girl maintained a vision of 20/40. The girl left the country for three years. When she came back she was wearing myopic glasses of 2 diopters, which were prescribed by an ophthalmologist using cycloplegic drops. Even though these drops are supposed to entirely eliminate functional myopia, Rakusen found that much of the myopia was indeed functional, since he was, after one year, able to reduce it "by more than a half" using plus lenses for reading.

Another optometrist, O.D. Rasmussen, from England, also advocated using plus lenses to deter the development of myopia. In 1954 he published an article wherein he shares the following case histories as presented to him by a colleague optician, who, instead of filling the minus-lens prescription that the patients came with, gave them plus lenses for reading. Here are a few of the case histories:

Miss H. Typist. Had few changes of lenses, gradually increasing in power, the last one being:

R.E. s -4.50 cyl +0.75 x 90
L.E. s -4.75 cyl +1.25 x 90

Her v/a for distance without lenses 6/24; with lenses 6/9. I refused to give such a prescription, and prescribed R.E. +1.50; L.E. +1.25, to be used for all close work. After three months her v/a without lenses for distance is 6/12. Change of lenses now due and expect 6/6 within 6 months.

Miss P.; Teacher. Brought Rx for O.U. -1.50, which I refused to give. Have prescribed for near +1.25 with suitable exercises. In three months her distance vision without lenses was normal.

Miss E.; Schoolgirl. I would not give prescription for R.E. -3.00; L.E. -2.75. Gave her O.U. +3.50. After three months her v/a for distance without lenses is normal.

American optometrist Jacob Raphaelson wrote and published a series of books detailing the advantages of the universal use of +1.00 glasses for everyone who does close work, as a way to prevent myopia and cure it in its early stages. One of the points that he brought out is that children start using their eyes at an extremely close distance even when their distance vision is normal. In 1934, he visited various schools and noticed that there was a marked tendency for children to bring their eyes closer and closer to their books or papers after only a minute or two. That year, in order to get some hard data, he did a survey of elementary schoolchildren in rural Clermont County (near Cincinnati). He measured how far they placed themselves from their close work (reading, writing) when they began, and at what distance they ended. He found that of the total of 503 children he observed, 80% used their eyes at a distance of six inches or less from their work. The following table is from Raphaelson 1956, p.84:

Distance	# Started at	(%)	# Finished at	(%)
10-12 inches	287	57%	2	00.2%
6-10 inches	205	41%	76	15%

3-6 inches	11	2%	331	66%
3 or less	0	0%	94	19%
Total	503	100%	503	100%

Raphaelson also found that while practically all the pupils were using their eyes at six inches or less from their work, only 5 out of the 523, or 1% of the students had myopic refraction. Furthermore, 84% of the students had 20/20 unaided distance acuity. He then had the children with poor vision (20/30 or less) wear plus lenses for five or six minutes. He found that of the 77 children with poor vision, 43, or 55%, had their vision improved and 22, or 29%, had their vision restored to 20/20 vision.

Raphaelson concluded from his experiments that near-seeing requires much effort and energy for young, hyperopic eyes. The strain on the eyes due to the continued close focusing causes a reduction in vision. Unfortunately, the solution to the optical problem causes an aggravation of the physical problem:

At the start, normally, the eyes use primary or central vision, but the eyes soon tire. When the children bring their eyes closer and closer to their work, they get assistance from secondary vision (peripheral) which functions better closer to the eyes, thus making it easier for them to see. This habitual use of secondary vision which requires more optical contraction will, sooner or later, make the child near-sighted, poor-sighted and astigmatic. [1961, p. 123]

He argued that it is difficult to maintain focus at 12 inches:

The near-vision survey also indicated that prolonged near-seeing affects our children adversely in many other ways. For, many of them not only began to bring their eyes closer and closer to the book or paper, but also began to frown and wrinkle their foreheads or turn their heads sideways. This should be proof enough to any unbiased person that prolonged near-vision is not effortless for small children but a real task.

Raphaelson, like Rakusen, was convinced that much supposedly structural myopia is actually functional, inasmuch as it can be cured by the use of convex lenses.

Although Raphaelson could not prove that near-seeing causes permanent myopia, his study and that of Rakusen are revealing in that he showed that a large percentage of schoolchildren suffer from subnormal vision that could be relieved by the use of plus lenses occasionally, or for periods of intense close work. Given the most widely accepted theory of how the eye focuses, such actions could apparently only handle the "ciliary cramp" type of myopia -- functional myopia. However, if functional myopia leads to structural myopia, as the close work theory proposes, then such lenses, used for all close work, would also prevent structural myopia.

Distant vision practice

Another method of preventing and eliminating functional myopia worth mentioning is daily reading of a distant eye chart, as advocated by William Bates (1911, 1913, 1920). Bates found that if students would refer to a distant, familiar Snellen visual acuity chart whenever distant objects became indistinct, they would regain control of their ability to focus. He first introduced this technique in a school in Grand Forks, North Dakota in 1903. According to

his account, he came upon the technique when testing the eyes of children at a school. Sometimes, children who failed the eye test at first would ask to be retested, and pass. Children who were known to be nearsighted would be able to read not only the test card, but writing on the chalkboard and distant clocks, which they had been unable to see clearly before. On the basis of this observation, eye charts were installed in the classrooms, so that there would be a familiar object on which to practice distance vision. In the first school system in which this technique was used, myopia -- as determined by examination "during a study period while [the children were] sitting in their seats" -- was reduced from 6 percent to 1 percent (1911). In 1912, he brought the technique to the New York City public schools.

It is important to note that Bates did not claim that myopia is caused by too much close work. Rather, he identified the "effort to see distant objects" as the sole cause of myopia (1913). "Near use of the eyes is not a cause of myopia," he insisted. This unique stance is based on his observations of people making efforts to see under adverse conditions:

It has been repeatedly demonstrated with the aid of the retinoscope that all school children with normal eyes when regarding the unfamiliar writing or figures on the blackboard, distant maps, diagrams, or pictures had myopic refraction. It was quite otherwise when they regarded a familiar distant object. The retinoscope used at the same time indicated no myopic refraction. (1913)

In other words, faulty distance focusing is a habit encouraged by trying to see distant objects. This "myopic response" to difficult viewing situations was widely recognized in Bates's day. In 1914, Walter B. Lancaster wrote: "when the patient strains to see, he exerts his accommodation and so sees better with a lens which permits or encourages this accommodation." However, Bates attaches unusual significance to this response and made it the cornerstone of his anti-myopia strategy, which was to encourage schoolchildren to focus properly for the distance by having them practice daily with a familiar distant object -- the Snellen test card. The method was the following:

A Snellen test card was placed permanently where all the pupils could see it from their seats. Daily the teachers recommended all the children to silently read the card with each eye separately, covering the other eye with the palm of the hand in such a way as to avoid pressure on the eyeball.

Records were made with the same card or with an unfamiliar card for testing the vision. (1913, 410-11)

Bates felt it was important that the test card be constantly in view and memorized, so as to make it as easy for the children to focus on as possible, and encourage them to focus properly:

It was only when the eyes were properly adjusted for distant vision that the small letters were read. With other distant objects children had greater difficulty in knowing when the focus was adjusted accurately. Many persons with normal eyes believed erroneously that they saw better at the distance by partly closing the eyelids or by otherwise straining the eyes; but, when they looked at the Snellen card, they at once discovered that the effort made the letters indistinct (1911).

Often it was most convenient to test the vision with the very same memorized card. Understandably, the value of a memorized Snellen card was met with skepticism by the authorities at the schools where he tested the technique. To assure them that the memorized card could be an accurate test the vision of the children, in January of 1912, the principal of one school had the vision of 1,500 pupils tested first with the memorized card, and then with an unfamiliar card. Bates does not report the exact difference in results the two tests, but says that the principal, in a

letter to the Superintendent, noted that Bates had "to a certain extent proved his point." Bates reports that in June 1913, the test was repeated, and,

the memorized Snellen card was again found satisfactory for testing the vision. Objective tests were conclusive, and demonstrated the interesting fact that school children did not deceive themselves or others, when their vision was tested with a memorized Snellen card. When a pupil said he was reading the memorized Snellen card with normal vision, the retinoscope used at the same time, indicated no manifest error of refraction; the eye was adjusted for normal vision. (1913: 411)

Other controls were also made from time to time, to verify that the training method worked:

Comparative tests were made with and without cards. In one case pupils with defective sight were examined daily for one week without the use of the test card. No improvement took place. The card was then restored to its place, and the group was instructed to read it every day. At the end of a week all had improved and five were cured. In the case of another group of defectives the results were similar. During the week that the card was not used no improvement was noted; but after a week of exercises in distant vision with the card all showed marked improvement, and at the end of a month all were cured. In order that there might be no question as to the reliability of the records of the teachers some of the principals asked the Board of Health to send an inspector to test the vision of the pupils, and whenever this was done the records were found to be correct. (1920:264-65)

Bates summarized the data from the New York City schools in two tables, reproduced below. PS = Public School # T = Number of pupils tested twice D= Number of pupils with defective vision at first test. I= Number of D in whom one or both eyes improved at second test. N= Number of D in whom both eyes were normal at second test. W= Number of T whose vision was worse at second test Te= Number of teachers Test Dates= Months in which the first and second tests, respectively, were administered during the school year of 1912-13.

If, then, we can trust these figures, it appears that poor distance vision can be overcome in the classroom. How much of this improvement can be attributed to a decrease in myopia and how much can be attributed to an increase in acuity or perception for other reasons, is not clear. The extent of improvement for any given student, in terms of either refraction or acuity, is also not clear at all from these statistics. However, some of the qualitative reports from the teachers give one reason to suspect that practicing with the eye chart daily helps keeps the eyes in working order. For example:

June 27, 1913, Miss Dillon was asked her opinion of the method.... She described in detail the results obtained. Some pupils, even with glasses, were unable to see the writing on the blackboard from their seats. In a short time their vision improved without glasses, so that they had no further difficulty with their sight. Others complained of eye pain or had trouble in seeing to read. They held their books close, about six inches from the face. The use of the distant Snellen card gave them relief and they later read without effort or discomfort at a comfortable distance, about twelve inches. She discarded glasses and relieved her own eyes by the use of the Snellen card.

More recently, a preliminary experiment has been done (Leber & Wilson 1994) with a computerized eye chart training system. After only five hours of training, six of seven myopes had "confirmed myopia diminution of -0.25D in one eye, two had improvement in both eyes." Furthermore, one subject "displaying pre-training 20/100 distant acuity in both eyes, recognized 20/80 letters after five hours of training and 20/50 letters after another five hours' training."

Many authors have tried to explain such successes as "purely psychological" or as the result of "blur interpretation" (e.g. Gibson 1953), since such improvement in acuity is not always attended with significant differences in refractive error as determined by a retinoscopic test of refraction at 20 feet, under cycloplegia. However, even if such practice cannot reduce existing refractive errors, there is the possibility that constant practice at focusing accurately for the distance reduces the spasm of the ciliary muscles and increases the circulation of blood in and out of the eye, improving acuity (and reducing the need to bring work materials close to the face) and, by preventing congestion and nervous disturbances, preventing structural myopia.

Treatment of Myopia -- Nutritional solution

Gardiner's observations on the connection between a low protein diet and myopia (1956) led him to use an increased protein diet as a treatment for myopia (1958). He performed a one-year experiment. The experimental group consisted of children of varying ages -- from 5 years to over 13 years -- and varying initial refractive errors -- from 0.25 to over 2.00 diopters of myopia. Their present diets were evaluated and then they were advised to change their diet so that the animal protein content was raised to 10%, leaving the caloric intake the same. The control group, composed of a similar population, was given no dietary advice. Gardiner found that, controlling for both age and initial refractive error, myopia in the experimental group progressed more slowly than in the control group in all cases except for the oldest children when the initial amount of myopia is small. The results are summarized in the table below, with change (D) indicating the average progression of myopia in diopters.

Table: increases in myopia with and without dietary changes.

Initial Myopia (D)		.25 to 0.9		-1.0 to -1.9		-2.0 or more	
AGE		N	incr. (D)	N	incr. (D)	N	incr. (D)

Treatment of Myopia Today

The idea of using plus lenses or distant vision practice to stop functional myopia before it turns into structural myopia, and the idea of diet or general health as a factor in myopia, are absent from the characteristically pessimistic modern literature reviews on myopia control (Goss 1983, Grosvenor 1987, Sivak 1991, Goldschmidt 1991). Methods currently being studied to control myopia are primarily biofeedback and bifocals. In the biofeedback technique, an expensive piece of equipment known as the Accommotrac (developed by J. Trachtman) is used to help the patient gain voluntary control of accommodation. This device measures the refraction of an eye and converts it into a tone. It is thought that by gaining conscious control of accommodation, one can thereby expand one's range of accommodation and see farther. Some experiments (Roscoe 1987, Randle 1988) show that myopia can be reduced by about a quarter of a diopter with biofeedback, while other experiments testing the Accommotrac in particular (e.g. Koslowe et al, 1991) reveal no significant difference between the control and experimental subjects in degree of myopia reduction.

Bifocals, which allow the wearer to do close work without looking through a full distance correction, are supposed to slow the progression of myopia in children. This technique has been around since at least the 1930s (Grossman 1949). Such glasses are designed so that every object looked at is comfortably within the child's range of accommodation. They differ from regular glasses in that they allow the child to use less accommodation to look at close objects, when looking through the lower half of the glasses, as when reading. The purpose of bifocals is to reduce the amount of accommodation required for close work, and not to force a reduction in accommodation for distance work, curing functional myopia, which is what a pure convex lens and distance vision practice approach is designed to do. Bifocals are prescribed on the assumption that the myopia diagnosed is completely structural and incurable; however, it is thought that the myopia can be kept from getting worse by reducing accommodation for near work. As David Goss (1994) notes in a review of experiments with bifocals, the effects are hard to generalize. Children who wear bifocals as opposed to single vision lenses still tend to progress at the rate of a quarter to a half a diopter per year. Goss notes that the bifocals only have a consistent effect on nearpoint-esophoric patients, that is, those whose reflex to cross their eyes when focusing on a near object has been exaggerated (their eyes over-cross in response to close focus, and extra energy is needed to keep them apart.) Esophores, Goss notes, seem to have a higher rate of myopia than other phoria types with single vision lenses, and a lower rate of myopia progression with bifocals. However the differences are statistically insignificant, and the average for all categories of myopes, no

matter which kind of corrective spectacles they get, falls between 0.25 and 0.55 diopters a year.

Summary and Conclusion

A range of explanations for myopia has been given throughout the years. Before the middle of the twentieth century, myopia in all its forms was often recognized by health authorities as a sign of ill health. Now it is coming to be recognized as a fact of life, and only high myopia is considered a health problem. But even though most myopes don't consider their myopia as something "wrong" with them, given a choice, they would choose to enjoy the prime of their life without dependence on glasses or contact lenses. Early research was based on the idea that myopia is largely a result of choices: of what to do with the eyes, or of what to eat. Modern research is based on the presupposition that myopia is a matter of genetic destiny, and nothing can be done to prevent it, but with a dim hope for some pharmaceutical breakthrough, and minor consolation in the prospect for surgical correction. The modern message is, "myopes, you have no choice but to be myopic and to grow ever more so." However, a few promising past theories on how to prevent myopia, especially ones that link structural and functional myopia, remain untested.

Notes

The Orinda Study

The study of Zadnik et al. is especially inadequate, and since it is today so widely cited in support of the genetic hypothesis, a discussion of its weakness is in order.

First of all, although Zadnik et al. made an attempt to account for close work in their model (they concluded that close work was a "modest" component), there are many types of close work not included in the "diopter hours" variable of Zadnik et al. for example, practicing piano, building model airplanes, solving jigsaw puzzles. Secondly, Zadnik et al. did not look at the time spent doing far vision activities, and did not consider diet. Thirdly, the exact refraction of parental myopia was not considered at all, but determined as a categorical variable (neither, one, or both parents myopic) on the basis of whether or not the parents were prescribed glasses for general or distance use before the age of 16. Thus, not only were a certain number of myopic parents who hid their myopia until driving age counted as nonmyopic, but those with glasses for hyperopic astigmatism and accommodative esotropia were classified as myopic. Precise correlations between refractive errors of the children to their parents could thus not be made. Fourthly, years in school was used as a proxy for age (even though the exact age of each child was known), making it impossible to differentiate between the "years of schooling" factor and the "growth" factor. Moreover, it was treated as a categorical, not continuous variable. Fifthly, for degree of refractive error, only three numbers were given, one covariance-adjusted mean for each of the three "parental history of myopia" (number of glasses-wearing parents) categories. Thus the "average" child of two myopes is 0.11D hyperopic myopic, the average child with one myopic parent is 0.51D hyperopic, and the average child with neither parent myopic is 0.62D, where the age is calculated according to an unspecified linear model that adjusts for grade in school and diopter hours. In other words, the averages are not subclassified by grade and diopter-hour range, so it is impossible to tell at which age the difference becomes significant. Furthermore, no indication of variance or distribution was given for these figures.

17) Are There Other Factors May Affect Your Vision and Vision Training Practices?

18) Can I Keep Doing This Forever?

19) Do I Need To Understand all the Unfamiliar Technical Terms used to Describe Vision and Vision Therapy?

20) Is Vision Therapy A Scientific, Medically accepted Practice?

21) WHO Can Benefit From These Exercises?

22) Are There Any Other Things One Might Do To Improve Vision?

23) What Books Are On Your List of Suggested Reading About Vision?

APPENDIX A GLOSSARY OF USEFUL TERMS

APPENDIX B SUGGESTED REFERENCES

APPENDIX C MEDICATIONS WHICH AFFECT THE VISUAL APPARATUS

1) What Is Vision Training? (also known as vision therapy, visual training, behavioral optometry, developmental optometry) It is a kind of physical therapy, or rehabilitative therapy for the *brain and eyes*. It is a progressive program, meaning that the beginning exercises are the easiest, gradually becoming more difficult, so that the flexibility and coordination of the eye muscles is improved. Students of vision training learn to control their eye muscles and are able to overcome many kinds of vision impairment which involve the muscles of the eyes. It involves improving visual skills such as eye teaming, depth perception, tracking, and vision-body (eye-hand) coordination. (See also [orthoaptics](#))

Most people who visit an optometrist know that any eye health problems will be detected and managed and that glasses or contact lenses will be prescribed if indicated. However, there are visual conditions that are best managed by optometric vision therapy. Some of these conditions are are weaknesses that a person is born with. Others are caused by accident or trauma. And of course the eye muscles and other parts of the eye will gradually weaken as a natural consequence of the aging process. This therapy enables an

individual to learn more efficient ways to perform visually. It is a valuable adjunct to the prescription of eye glasses, contact lenses and the treatment of eye disease.

2) Is This a Brain Problem Or An Eye Problem? It is *both*, because the visual system involves the brain as well as the eyes. The eyes are literally physical extensions of the brain. Binocular vision problems may involve difficulties with how the brain processes visual info coming through both of the eyes.

3) What Is the History of Vision Training? How Long Has it Been Available? Vision therapy is not new. Physicians in the mid-1800s originally introduced many of the techniques that are used today. Modern Optometric Vision Therapy was introduced in the United States in 1928. Throughout the years, vision therapy has been called various names such as visual training, orthoptics, or eye exercises.

4) Why Doesn't Everyone Know About Vision Training? First of all, Vision Training is well-known in many parts of the world, but is best known with respect to vision problems in children. We have all seen children with strabismus, where the eyes are crossed. The daughter of one of my best friends had this condition, and it was corrected through the use of vision training. Children with attention deficit disorder often have difficulty with eye muscle coordination. The benefits for adults are well-documented, but are simply not well-known *yet* by the general population. But everyone knows the value of exercise in general. The practice of yoga, for instance, is well known to produce benefits in muscle flexibility and coordination. If practiced consistently, it helps to slow down the deterioration of one's muscles which are a natural consequence of the aging process. Vision Training will have this effect as well, but it targets the visual system. It requires persistence, more than anything else, but the benefits are enormous.

5) How Can I Tell if I Could Benefit From Vision Training? First of all, you know your eyes better than anyone does. Think for a minute about the *variability of of your vision*. Do you see better at some times than at other times? This suggests right away that whatever is imperfect about your vision is not a *fixed* thing. If you recognize this, there exists the possibility that muscle weakness, fatigue, and coordination problems may be at least part of your problem. Get a comprehensive eye exam, so you know if there is anything *else* afoot. There are eye conditions that there is no remedy for, and you will want to rule these out. If you hear the good news from your eye doctor that you do not have one of *those* conditions, like cataracts, glaucoma, or retinopathy, it is likely that you can benefit from vision exercises. Even if the doctor says that you are aging, and your lenses are less flexible now, there is hope that you can improve your vision.

6) How Do You Know That I Can Do It? I think you can do it because *I* was able to do it, and at an age when I was told that it probably was too difficult for me; I was too old. But I am a jewellery modelmaker, and I needed my eyesight to be very good for my work, and I needed my eyes to be strong so that I didn't suffer when I was using all that magnification equipment. I saw that my eyesight was getting worse and worse, for both close work and distance vision. I needed glasses to read, even if I hadn't been using my eyes much, and when I wasn't even tired. I was kind of desperate, actually. So I decided that it was worth the effort involved. Please remember that it is absolutely essential that you have a comprehensive eye exam before you seriously undertake vision therapy exercises. I cannot stress this enough. There is always

the possibility that you may have an underlying condition that cannot be improved through vision training, and this first has to be ruled out.

7) How Did You Know About Vision Training? What Is *Your* Personal History? I had known about it for years, because my family optometrists, Dr Evans and Dr Stein, are people I have known for my entire life. I would sometimes be in the optometrist's chair, and Dr Evans would entertain me with stories of baseball leagues who sent some of their players to him to see if they could benefit from vision training. It seems that some of them were having trouble in the outfield, etc. He told me that on testing them, he could tell if their problems could be remedied through vision training. I never thought about having vision training myself, because I was lucky enough to be born blessed with very superior eyesight, much better than 20/20. I could see well at almost any distance, in dim and bright light. Many people are fortunate like this when they are young; others are not. But when I was about 33 years old, I suffered an eye injury on the job. I was working in a jewellery factory, without any glasses or goggles on to protect me, and a piece of metal broke off of what I was working on. It hit me in the right eye. It damaged my cornea, which is the clear covering over the front of the eyeball. I had to have emergency surgery to remove bits of metal from my eye, and I had a bandage on for awhile. After that my vision wasn't as good, but I really didn't want to think about it too much. Some time later, Dr Evans examined me and informed me that my eyes were not working in concert with each other. He said that my ciliary muscles which are used to focus the lens of the eye were in spasm, too, from the shock of the accident. He frankly didn't know how I was even able to do my work with that problem, and recommended vision therapy. When I started my therapy, I was forced to confront the inadequacies of my eyesight, and it was very upsetting to me, emotionally. I was given various procedures to practice in the doctor's office, and lenses to practice with at home. I found everything very difficult, and I was also forced to notice exactly how long it took me to focus the eye that had been damaged. There was a lapse of about 5 seconds in focusing, and when I finally did manage to focus, the image that I saw with my right eye was considerably smaller than the one I saw with my left eye. Mercifully, I did not suffer any permanent scarring of the cornea, since I somehow absorb scar tissue. Another bit of luck. This time I really needed it. I continued with my therapy for some time, but frankly I was not too dedicated. I was able to improve my focusing ability and the ability to use my eyes in tandem with each other. The next time I underwent therapy, I was much more determined. I was 45 years old, and both my near vision and distance vision were getting progressively worse. I didn't want to go to see Dr Evans, because each time I went I needed a stronger prescription, just to read the newspaper. I kept using more and more magnification for my modelmaking work, and my eyes just felt *so* uncomfortable after doing this. I decided to try vision therapy again, although I was told that it would probably be too difficult for me since the flexibility of the lens was no doubt affected, due to the aging process. When I started my exercises I once again had a great deal of trouble, but somehow this made me more persistent and creative in my approach to it. I had difficulty with even the easiest lenses, so I tried doing things a different way than suggested. For example, instead of using a lens with a small reducing factor, I held the newspaper closer and closer to my eyes. This helped to "coax" my eyes into improvement. Soon I was able to use the practice lenses. There were many other things I tried, but most of all I decided to take notice of every single detail in my practices. I realized that being hyper-aware of what my eyes were doing was of utmost importance. Especially when I found something that *worked*. I will give many details of my vision therapy practices in the pages that follow. Most of these were homework ordered by Dr Evans and his partner, Dr Stein. Others are culled from the writings of other

people who have had vision problems, and of course I came up with a few useful ideas myself. The result of all this? I practice vision exercises every day of my life, and I have been told that I now have the eyes of a 25-year-old. I have heard many anecdotes of successful vision therapy in other people, too. I am not the exception. And I think that you all could succeed at it, too. The benefits are too great for you not to give it a chance.

8) What Is The Bates Method of Vision Improvement? Is There Anything Useful in It? I had so much trouble with the regular vision training homework, as I stated before, that I did look into it when I started training again, at age 45. I *do* find it useful, to a certain extent. I read about the Bates Method in a book by Aldous Huxley, called *The Art of Seeing*. I knew that Huxley was a brilliant man; I had read many of his novels, and I had heard that his book on the Bates method was easier to understand than the one written by Bates himself. When Huxley was a teenager, he suffered an attack of *keratitis punctata*, an acute infection which left him with opacities in his cornea, farsightedness, and extreme blurriness. He was actually almost blind for 18 months. After that, his vision was still extremely poor; he was barely able to detect light with one eye, and only just barely able to see the largest letter on the Snellen (eye) chart at 10 feet. He used a hand magnifying lens at first, and then was promoted to eyeglasses. He suffered continual strain because it was such a strain to see *anything*. After some years he suffered a worsening in his eyesight, and fearing eventual absolute blindness, investigated some methods of visual improvement that he had heard of. He wrote very eloquently on the benefits of Dr Bates' methods, and those of his disciples. Huxley's book details his ability to read without glasses and without strain and fatigue through the use of these methods. My own experience was not quite so pronounced, but I certainly did find some of the Bates practices quite useful. This is especially true when one's eyes are middle-aged and need to be *coaxed* into "working out." Please be reminded that this essay is not a wholesale endorsement of the Bates Methods. They are a good start when one finds standard practices too difficult. The actual vision training exercises are more challenging, and I believe that they are necessary for the optimum recovery and improvement of visual functioning.

Some of Huxley's observations follow

- a) Ophthalmologists are obsessed with the physiological side of seeing; they ignore that there may be a *mental* aspect to vision.
- b) When conditions permit, a sick organism tends to recover through its own intrinsic powers of healing. In other words, without the existence of natural healing powers, medicine would be helpless.
- c) Artificial lenses do not eliminate the causes of defective vision. eyes fitted with these devices tend to become increasingly weaker and to require progressively stonger lenses for the correction of their symptoms.
- d) A good teacher can often educate a victim of paralysis or accident into gradual recovery of function. If such things can be done for crippled legs, the same can be done for defective eyes.
- e) Heightened powers of perception can improve a person's capacity for sensing and seeing.

- f) *On the Variability of Vision*** Defective eyes can have flashes of normal vision under a situation involving "dynamic relaxation."
- g)** The wearing of glasses confines the eyes to a rigid and unvarying state in which flashes of normal vision are quite impossible to detect.
- h)** Any inhibition of eye movement (such as staring, or immobilization by wearing glasses) lowers the powers of seeing.
- i)** Staring produces *tension* and psychological strain, and normal vision becomes impossible. When *continuous and excessive tension* is present, circulation is reduced, and the tissues of the body lose their resistance and their powers of recovery.

[Some of the practices I have adapted that Bates and Huxley developed are described in [Section \(13\)](#)]

9) Can You Describe a Typical Vision Therapy Session In Your Doctor's Office? A qualified vision training specialist (**or *provider***) is usually an Optometrist, who is by training an expert in the use of lenses for vision correction. The first step is of course a comprehensive eye exam. The results of this will first of all indicate if a disease process is present which would not be improved through vision training. They also will reveal what weaknesses the potential vision training patient possesses, and will suggest what machines should be used and to what parameters they should be set if vision training is to begin. The vision training "laboratory" environment consists of many devices which contain lenses and prisms. These challenge the eyes and force them to work to produce coherent images using both eyes. Eyeglasses with colored lenses and polarized materials are also used in a similar manner. The beginning vision training patient will commonly experience strain when the eyes are thus challenged, and the eyes will shed tears. This effect will lessen as he becomes more adept. He learns to observe what his eyes are doing and to be aware of the feeling he experiences when his eye muscles are being worked, and when he is successfully able to see an image correctly. In time, he is able to discern what muscles are being worked. The computer is also used in training. The doctor will set up sessions in which the patient is given progressively more difficult things to do with his eyes. Some of these may involve the eyes having to rapidly focus at near and distant objects. Another has the eyes following objects moving around the monitor screen which appear at different distances. Doing this makes one aware of exactly which muscles are weak, and must be worked on. This all sounds so complicated, but good results are often dramatic and rapid. Actually, a common effect of training is that you can see a bit better after just the first vision training session, even if you have a great deal of difficulty succeeding with the office vision training practice. The vision training session exercises both the muscles inside the eye, which change the shape of the lens, and those outside of the eye. Both muscle groups must work in concert with each other for vision to be optimal. And a crucial part of vision training is home practice. Your vision training specialist will give you lenses, prisms, and cards for you to use at home. Commonly, one uses a lens to exercise one eye at a time, and after both eyes have become stronger, a "flipper" is used which challenges both eyes to focus at

the same time. The use of these home devices is prescribed by the doctor depending on what the patient's visual weakness is. I can give you details of my own practices, but unless you all have exactly the same eye problems as I do, your practices would be somewhat different from mine. And as I stated before, I also recommend the Bates method as a starting point, especially if vision is very much impaired, or if the patient is as old as I am!

10) What Parts Of The Visual Apparatus Are Involved In Vision Training? Basically, the lens, the ciliary (intraocular) muscles, and the extraocular muscles. The brain itself is of crucial importance, since the information the eye receives is transmitted to the visual cortex via the optic nerve. The eye apparatus is the input device. All seeing actually takes place in the brain, as this information is processed. (Show Schematic Picture of Eye and other diagrams, of lens, etc *short* description of eye anatomy and brain involvement)

11) How Is It Possible That You Can See Better, If You Don't Do Well In Your Office Practice Or Home Session? There is a mathematical concept called a "limit." A limit by any definition is something which is the maximum that can be achieved. A mathematical formula can often be depicted visually as a "function." A logarithmic function is a curve (see diagram) that reaches into infinity and never quite reaches the line called its *limit* or *asymptote*. Well, vision training exercises often put one's eyes through extreme motions that are actually quite unnatural, in order to strengthen the eye muscles. When the patient does not see the image with *complete* clarity, (the limit) he has often nonetheless improved his abilities. In my own experiences (in my home practices) I was unable to see images clearly when using some of the reducing lenses. Nonetheless, I found to my surprise that after using them for a time I no longer needed reading glasses. My goal was perfect clarity through the lens, and my vision *did* improve, although not to that absolute limit.

12) What Are Some Easy Vision Improvement Practices One Can Do Without Special Equipment? First of all, sometimes one is waiting for a bus or is on a train, and stranded without your home vision training materials. An excellent idea for someone with accommodative insufficiency, like me, is to focus on something very close, like a brooch or button on your coat, and then to look at something very far away. You can feel that your extraocular (outside) eye muscles first turn your eyeballs inward, and then outward as you look at some far-distant object. The ciliary muscles inside the eye must also work in both cases, changing the shape of the lens, trying to see the object with clarity. This is true regardless of how near or far the object you are focusing on is. Another practice is to do this with one eye at a time. Both eyes must be utilized for proper vision, but I have found this to be useful in determining the exact weakness one has. Once you can determine your weakness, you can devise methods to work the eye to improve it. If one has a weakness in *near vision*, try moving the newspaper closer than you usually can see it comfortably, just a bit. This is actually a much milder exercise than using a reducing lens. Try taking off your reading glasses, if you have been in the habit of using them. And try to relax, and scan the page of a newspaper or book. You can often see more than you would have expected. The same result is achieved if you try to look at print that is a bit too small to read, or the locations on a map. Blinking your eyes a few times will help them to focus. You can often discern words, unexpectedly. You can find objects to practice with everywhere. The small print on a medicine bottle or on an advertisement, or a magazine that is printed poorly with not enough contrast in colors. You can move the page closer than you can see comfortably,

also. Another good exercise is to look up and down, left and right, without moving one's head. This stretches the muscles that move the eyeballs. A good exercise for those muscles to do on the computer is to read a very long line of type, backwards and forwards, without moving the head. You will feel your extraocular eye muscles working. *Find out what your visual weakness is, and work on it all the time. This is the real secret to success in vision therapy, for who has time for a designated practice session all the times you should be doing them? The key is to do some form of vision exercise every single day.*

13) What Are Some Bates Methods and Observations I Have Found Especially Useful? Many specialists object to Bates and consider his methods useless. In my opinion, they are based on common sense, and the proof of this is that many of them have been entirely incorporated into standard vision training therapy. I believe that they are a very good starting point, but not challenging enough to produce as much vision improvement as can more modern practices utilized by vision training specialists. That is, unless one's eyesight is as impaired as that of Aldous Huxley. It is likely that standard vision training exercises would have been too difficult for him.

a) **Boredom is a cause of visual malfunctioning.** Try whatever it takes to make your home practices interesting. For instance, early in my training I was given a page of the telephone book to practice on, using reducing and magnifying lenses. I couldn't bring myself to do this regularly; it was so boring. Then I started switching the lenses as prescribed, but while reading an interesting book. I progressed rapidly from there, and was able to increase the length of my practice sessions as well.

b) **Palming A Relaxation Technique** The eyes are closed and covered with the palms of the hands

c) **Breathing And Blinking** the quality of circulation around the eyes can be enhanced by breathing without strain and natural blinking habits. Blinking also serves to lubricate the eyes

d) **The Usefulness of Light** We have an unnatural fear of light; sunning the eyes is a valuable technique

e) **Procedures to Encourage Mobility** Swinging, shifting, flashing

g) **Memory As An Aid To Vision**

h) **Specifics Myopia, Hyperopia, Astigmatism**

i) **Some Difficult Seeing Situations** Reading, Looking at unfamiliar objects, movies

14) What Home Practices Does The Vision Training Provider Prescribe? (See Practice Guide (link forthcoming).)

- Lenses
- Cards
- Software

- Other (customized)

15) What Side Effects May Result From Your Practice of Vision Therapy? Think of what occurs when you undertake almost *any* new form of exercise. One result can be discomfort. Your eyes may feel "tight," and will probably water a good deal when you are working on some particularly difficult exercise. I find that this subsides over time. You can also experiment with your practicing schedule. For some people, more practice sessions per day are easier. And vision exercises can be done during a break in your work schedule. For example, after doing taxing close work with a lot of magnification, you may feel better if you do some exercises in which you are gradually diverging your eyes. You will also most likely see almost immediate improvement after your first training session with your therapist. *You can see better.* You didn't think it possible...but it happened. But you have to keep doing it. You can expect improvement if you practice diligently, but if you stop for any length of time, *you will backslide.* Many of the exercises are unnatural motions for your eye muscles. This is intentional, so that the muscles can grow stronger and more flexible in response. Your everyday average activities will not have the same therapeutic effect on your eye muscles.

16) What Is A Typical Day Like For You, In Terms of Practicing Vision Exercises? There is no typical day. Every day is different. I have this piece of software now that I find a lot of fun, since it's hard to get me away from the computer, anyway. On days that I use the software, I do Base In Vergence, which is hardest for me, because my eyes like most of all to converge. Then I do Base Out Vergence, Autoslide Vergence (which is both BI and BO) and Jump Distance, which is the very hardest. I try to do this more than once. Some days I stick with lenses. I have been instructed to use minus lenses, to make my eye muscles work better at near vision, because modelmakers need to be able to see at close range very well. I get bored reading the phone book (as my doctors told me to do) so I use a minus lens on one eye at a time, reading a good novel, and starting at - .75 and working my way up to lenses that reduce even more. I use the flipper if possible, too, since it is what gets my accommodative muscles working together. When I'm working a lot, it is helpful when I take breaks to use the computer program and the prisms a bit. My prisms are for vertical shift problems, which I have also. I have improved at this, though, because I have more challenging prisms now. I don't do every single exercise every day. Sometimes I use the "coin cards." The plain ones are for practicing *Base Out.* I've made some of my own on my computer that are more challenging, with smaller coins. The transparent one is the hardest; it's for *Base In.* Anyone who can do this one well I take my hat off to you! It's very difficult, but after I (at least try to) do it, I really do feel my eyes can focus much better. Sometimes I have to spend a whole day seeing customers and riding the subway. So I look at something very close, even my fingernail or a button, and then far away. Like small print on a billboard. Of course there are some days when even that much is not possible, training-wise. So I take a book to bed, and use my minus lenses, one eye at a time, until I realize that I am reading in my sleep...

** Please remember that these exercises are designed for ME, with my particular vision problems. When you get your eye exam, or find a vision therapy provider, you may be told to do other exercises. Everyone is different.*

17) Are There Other Factors Which May Affect Your Vision and Vision Training Practices? If you

have any serious systemic medical conditions, such as diabetes or lupus, you may have additional eye or other problems. Your doctor will be the best judge of whether eye exercises will be too difficult for you, in this case. And some conditions specific to the eyes, such as glaucoma, cataracts, or macular degeneration are very serious. They cannot be improved through the use of vision training. But if you are basically in good health, and you are "warmed up," by walking or other exercise and your circulation is up, you may find that your eye muscles are at their most responsive. Caffeine often improves your exercise performance a bit as well. Watch out for this if you have high blood pressure. On the other hand, there are many drugs and medications which make your eye muscles temporarily weak (*see [APPENDIX C](#)*). So, if you are on some necessary medication, do not be surprised if you experience a temporary setback in your exercise program. Think of it this way You don't always have a good exercise day at the health club, but if you keep going, you will steadily improve, over time. By the way, your age is an important factor. I began training very late in life. Younger people can usually expect more rapid improvement in their visual functioning. Since I am a middle-aged person, I am battling of course what is called *presbyopia*, the hardening of the crystalline lens of the eye. I'm trying to keep it flexible for as long as I can...

18) Can I Keep Doing This Forever? Well, almost forever. But this life isn't forever. One can't really say at what rate the different parts of the body age. My doctors have some patients in their seventies who can still do vision exercises successfully. I'm lucky that my lenses still have enough flexibility that working my ciliary muscles is useful. Most people my age won't undertake something like vision training, so there is no "control," scientifically speaking. (**Explanation of the scientific method during lecture**) Any good exercise program will slow down the aging process, but of course we all will succumb to some illness or ailment eventually. Vision exercises will help slow the effects of aging on one's eyes, though, in many cases. Remember, I experienced this myself. My eyes had been worsening for both near and distance vision, and this has been reversed. I don't need glasses to read or to drive, now, and I can do acrobatics with my eyes, sort of. I can do things now that I couldn't do as a child when, of course, normal functioning of my eyes was so good it was completely effortless. The difference now is that I can *feel* my eye muscles working. It does take an effort for me, now, but it's not uncomfortable. I'm grateful that with this therapy, they *do* work well.

19) Do I Need To Understand all the Unfamiliar Technical Terms Used to Describe Vision and Vision Therapy? You probably will *want* to familiarize yourself with at least *some* of the terms. Many of them help to explain *what* you are doing when you practice the various exercises, and *why*. When you have your comprehensive eye exam, your doctor may tell you that you have "strabismus," or one of the terms that appears in the glossary (**SEE [APPENDIX A](#)**) It's been very helpful to me, knowing what is wrong with my eyes. It makes it easier to work on my problems when I know that I have "divergence insufficiency," for example, and need to be able to *feel* my extraocular muscles working in order to improve my condition. It makes a person feel a lot less...well...helpless. Especially when you encounter an exercise that is especially difficult. And many people are like this If you can visualize in your mind what your eyes are doing, you have the capacity to change and improve their functioning. Remember, this is an eye *and* brain problem. Anyway, since this worked for me, I think it will help you, too. And there's another thing Experts of all kinds like to toss around language that you can't understand. It makes a person feel kind of ignorant. I happen to think that people do this on purpose, for reasons of their own.

For instance, before I got a computer, people made me feel very small when they used computer terminology. Which turned out not to be all that difficult to understand, by the way. Well, with this essay and its accompanying glossary about vision, you will feel *empowered* with understanding about the workings of your eyes! Trust me; you'll feel alot better knowing this stuff...

(show diagram of the eye)

20) Is Vision Therapy A Scientific, Medically accepted Practice? Vision therapy is not voodoo or a magic act, but a very well-documented practice. See Scientific studies on vision therapy, at the Indiana University School of Optometry web site, and *Vision Therapy References* for other publications. (See also [Appendix B.](#)) It is akin to other types of physical therapy, and is most widely-known as an aid for children with vision problems. Many ophthalmologists think that vision therapy doesn't work., but they are primarily concerned with *diseases* of the eye, and with surgery. They are not required to learn about physical therapies for vision improvement, as optometrists are, during their training. Similarly, in the USA, medical doctors have no required training in herbal medicine or nutrition, and few of them consider learning about it to be worthwhile. So there is a rivalry between herbalists and medical doctors. Herbal medicine is very well-respected and researched in Europe, China, and India. MDs are ignorant of herbal medicine; ophthalmologists are ignorant of vision therapy. The problem is merely their lack of knowledge, and many professionals are loath to admit this. My answer to either situation is *Try it!* You may be quite suprised and pleased.

21) WHO Can Benefit From These Exercises? Anyone whose vision problems are related to muscle weakness or lack of coordination. The exercises take time, patience, and persistence. People whose work is especially stressful to their eyes, such as jewellers, designers, photographers, and computer users will find them especially valuable. *Below are some tips for certain professions*

Jewellers, Designers, etc

- a) Have a comprehensive eye exam. Having the proper glasses will prevent further stress on your eyes, since they will correct whatever is your particular weakness.
- b) If your vision does not need correction, wear glasses with non-corrective lenses. You will need to protect your eyes from damage due to possible accidents on the job.
- c) If your work requires better than 20/20 vision, have your eye doctor prescribe magnification lenses in your particular prescription.
- d) Frequently change the magnification you are using. This helps to prevent the lenses from losing their flexibility at varying distances.
- e) You may find it useful to use your prescription magnification glasses with optivisors, etc for additional magnification. Many people experience eye pain or discomfort when using non-prescription magnifiers.

The use of BOTH often remedies this.

f) Make sure that you have adequate lighting for your work, whatever is comfortable for you.

g) Take frequent breaks if your schedule permits, to practice vision training exercises of all kinds.

Computer Users

a) Have the monitor from 16 to 24 inches away from you. Excessively close computer work is a strain on one's eyes.

b) Frequently take a break from looking at the monitor, at least every 15 minutes. Look far away, at varying distances.

c) Use the largest monitor possible, with screen contrast, etc. so that resolution is maximized.

d) Location of Monitor The center of the computer screen should be 4 - 9 inches below your eyes. Your eyes work best with a slight downward gaze. If the computer screen is higher or lower than this, it causes an awkward posture that contributes to sore neck, back, or shoulder, and may also produce headaches. Also, your computer screen and other work should be located straight in front of you so that you don't have to look sideways or twist your body or neck to see them.

e) Lighting Bright lights or other bright objects in your peripheral vision can be uncomfortable. Use a relatively low-wattage bulb in your desk lamp if possible. Drapes can be used to shield one's eyes from daylight if necessary.

f) Look for anti-reflection screens that have been approved by the American (or other) Optometric Association.

g) Experiment Try varying the size and kind of typeface you use in your browser, word processing application, and other

programs during the course of the day. This serves as a kind of vision exercise itself.

h) Do vision training exercises as often as your work schedule permits. Vision training software is ideal for this purpose.

i) Blink on a regular basis; do not stare at the monitor. This sounds obvious, but people sometimes don't realize that they are staring. Blinking helps one to refocus the eye, and is also relaxing.

i) Get computer glasses if your eye doctor recommends this. These lenses are designed to accommodate the unique viewing distances and angles at a computer

22) Are There Any Other Things One Might Do To Improve Vision? Do whatever you can to remain in good health. It has been suggested that certain herbs and nutrients might promote the health of the visual apparatus. These include bioflavonoids such as quercetin and lutein, vitamins E, A, and C, and herbs such as bilberry. CoEnzyme Q10 is another. Any nutrient that has the reputation of having Antioxidant properties would be a good idea. Of course nutritional supplements of any kind are an added expense. The most important thing is to eat a balanced diet containing all the essential food groups. Essential fatty acids (oils) which are polyunsaturated or monounsaturated help especially the nervous system and hormonal systems. Many people try to eat a very lowfat diet to keep their weight down, but if you eliminate too many beneficial fatty acids, your health will suffer. Of course try to get enough rest and do whatever is your favorite method of relieving stress. And what one *doesn't* do can often have more of a good effect than anything else. Smoking and drinking are well known to promote rapid aging, as do recreational drugs (Sorry!) so they are also not a good idea. Try to live a life of moderation, in terms of eating well and exercising regularly, in general. If you know that you have a medical condition, like diabetes, make sure that you keep your sugar level under control. Vision problems related to blood vessel problems are related to this disease, among other things. And no one lives a perfect life, healthwise, but most of us know what is actually really *bad* for us...

23) Suggested Reading

* **The Art of Seeing** by Aldous Huxley

* **Stereogram** by Cadence Books *This book is a very good start for practicing Base In (distance) Exercises. Seeing Stererograms is much easier than regular training. It is also alot of fun!*

APPENDIX A: A GLOSSARY OF USEFUL TERMS

Accommodation- (eye focusing) the eye's ability to adjust its focus by the action of the ciliary muscle, which increases the lens focusing power. When this accommodation skill is working properly, the eye can focus and refocus quickly and effortlessly, which is similar to an automatic focus feature on a camera. The ciliary muscles must contract to adjust for near vision, which causes the eye's crystalline lens, which is flexible, to be squashed. For distant vision, the ciliary muscle must relax and the eye's crystalline lens is stretched out. The ability of the eye to accommodate does decrease with age due to the crystalline lens becoming less flexible causing a condition called presbyopia. (See [Presbyopia](#))

Accommodative Fatigue- This clinical condition is also called **Ill-Sustained Accommodation**. It is the inability of the eye to adequately sustain sufficient focusing over an extended time period. The most common sign or symptom is blurred vision after prolonged near work such as reading and using a computer. In addition, such patients often have asthenopia (eyestrain), general fatigue, headaches and nausea, excess tearing, and an unusual sensitivity to light. Clinical signs include normal amplitude of accommodation, decreased PRA, and the patient generally fails the +/-2.00 D flipper test. Plus lenses

(glasses or contacts) and vision therapy are effective in treating this condition.

Accommodative Esotropia- this clinical condition is an excessive inward turning of the eye caused by an overactive convergence response as the eye focuses on an object. More common in farsighted (hyperopic) children. This is treated with plus lenses (glasses or contacts) to decrease the accommodative demand and to straighten the eyes. In some cases, vision therapy and corrective lenses are prescribed. (Please note that Accommodative Esophoria is a condition similar to accommodative esotropia but lesser in extent.)

Accommodative Excess (AE)- This clinical condition is also called **accommodative spasm**. It is an over focusing, over stimulation of the focusing action of the crystalline lens causing an inability to relax the focusing system which may result in blurry vision when focusing at distance objects. Other symptoms include holding near work closer than normal, headaches with near work (such as reading or using a computer), eyestrain associated with near work, and possible double vision. Clinical signs include patient accepts more minus on accommodative rock but blurs with plus lenses, lower NRA than PRA, dynamic retinoscopy findings indication of over accommodation and/or slow relaxation of accommodation, and reduced or erratic distance visual acuity. Vision therapy is an effective treatment option.

Accommodative Infacility- (clinical condition) a difficulty changing eye focus from distance to near. Symptoms include eyestrain associated with near work (such as reading or using a computer), periodic blurring of distance vision especially following sustained near visual work, tendency to hold near work closer than expected, headaches with near work, and possible double vision. Clinical signs include patient will have difficulty with both the plus and the minus lens (fails +/- 2.00 D flipper test), low PRA and NRA, and poor recoveries on Bell Retinoscopy. Vision therapy is an effective treatment option.

Accommodative Insufficiency (AI)- This clinical condition is also called **non-presbyopic accommodative insufficiency**. It is an under focusing, a lack of focusing ability at a near distance. Symptoms include eyestrain, blurred vision, occasional or constant when doing near work (such as reading or using a computer), occasional unusual sensitivity to light, excess tearing, headaches, and general fatigue. Clinical signs include patient will have difficulty with a minus lens, low amplitude of accommodation, low PRA and higher NRA. Vision therapy is an effective treatment option.

Accommodative Vergence- a convergence response (to turn the eyes inward) which occurs as a direct result of accommodation. (See [Vergence](#) and also [Amplitude of Accommodation](#))

AC/A Ratio- accommodative convergence / accommodative ratio (measured in prism diopters/diopters). This is the numerical expression for the relationship between the amount both eyes simultaneously turn inward (converge) in response to an increase in optical power of focusing (accommodation) by the eye's lenses. The normal ratio is 4:1.

Acuity- sharpness or clearness of eyesight. It is a measure of the finest detail a person can see. The Snellen chart is used to test visual acuity. This chart contains rows of letters, numbers, or symbols in standardized graded sizes, with a designated distance at which each row should be legible to a normal eye.

(See ["Near Acuity"](#) and ["Distance Acuity"](#))

After-image- the eye's ability to still see an image during eye blinks and even after the viewed object is no longer present. The most common example is seeing light after the flash of a camera.

Alignment- proper fusing (uniting) of images to each eye.

Amblyopia- (also called "lazy eye.")The unexplainable loss or lack of full development of the vision in one eye. It is not fully correctible with glasses or contact lenses, and has not been traced to any particular eye health problem. Sometimes it is the result of crossed eyes or a great difference in the refractive (light-bending) error between the two eyes.

AMD or ARMD (age-related macular degeneration) Disorder characterized by the gradual loss of central vision due to a damaged macula (which is made up of retinal cones necessary for sight).

Ametropia- any optical error such as hyperopia, myopia, presbyopia, or astigmatism that can be corrected by glasses or contacts. Also called refractive error

Amplitude of Accommodation (AA)- a measurement of the eye's ability to focus clearly on objects at near distances. This eye focusing range for a child is usually about 2-3 inches. For a young adult, it is 4-6 inches. The focus range for a 45-year-old adult is about 20 inches. For an 80-year-old adult, it is 60 inches.

Aniseikonia- unequal retinal image sizes in the two eyes, usually from different refractive errors. (*See [Iseikonic Lens](#)*)

Antioxidant - Substance that inhibits oxidation and can guard the body from the damaging effects of free radicals. Molecules with one or more unpaired electrons, free radicals can destroy cells and play a role in many diseases. Antioxidants may help prevent macular degeneration and other serious eye diseases.

Aqueous humor - Clear fluid in the eye that both provides nutrients and determines intraocular pressure.

Asthenopia- eyestrain, symptoms include excessive tearing, itching, burning, visual fatigue, and headache. May be related to uncorrected refractive error, accommodation (eye focusing) disorder, or binocularity (eye teaming) disorder.

Astigmatism- Blurriness of vision at all distances, a common vision condition which is usually caused by the front surface of the eye having a slight irregularity in shape.

Base-Down (BD) Prism- the base (thickest end) of the prism is downward and it causes the eye to move up. Used to measure or treat a binocular dysfunction (eye teaming problem). Sometimes incorporated in glasses.

Base-In (BI) Prism- the base (thickest end) of the prism is towards the nose and it causes the eye to diverge (straighten or move out). Used to measure or treat a binocular dysfunction (eye teaming problem). Sometimes incorporated in glasses.

Base-Out (BO) Prism- the base (thickest end) of the prism is away from the nose and it causes the eye to converge (turn in). Used to measure or treat a binocular dysfunction (eye teaming problem). Sometimes incorporated in glasses.

Base-Up (BU) Prism- the base (thickest end) of the prism is upward and it causes the eye to move down. Used to measure or treat a binocular dysfunction (eye teaming problem). Sometimes incorporated in glasses.

Behavioral optometrist- A doctor of optometry who specializes in the practice of vision therapy. Also known as a *vision training provider*.

Bifocal Glasses- eyeglasses that combine two lenses with different refracting powers, one for distant and one for near vision. Often prescribed for people with presbyopia.

Binocular vision when both eyes aim at the same target at the same time, working together as a well-coordinated team, equally and accurately (See also [stereopsis](#))

Binocular depth perception- the ability to perceive with one's eyes that space has three dimensions, particularly depth. Also, the ability to judge relative distances between objects

Binocular vision impairment- a defect in vision in which one's two eyes do not work together as a well-coordinated team. This results in a partial or complete loss of binocular depth perception and stereoscopic vision. At least 12% of the population has some kind of binocular vision impairment.

Break Point- measurement, the point at which a person can no longer fuse (unite) two images into one.

Cataracts- A condition in which the normally clear lense of the eye becomes cloudy, resulting in clouded and or blurred vision. (Cannot be corrected by the use of vision training) Cataracts may be caused by aging, eye injuries, disease, heredity, or birth defects. Surgery is a treatment option. The affected lens is removed and is replaced with a substitute (implant) lens or with a special type of contact lens. Generally the success rate of cataract surgery is over 90%, if the eye is otherwise healthy.

Ciliary Body- a structure directly behind the iris of the eye and contains the ciliary muscle. (*See diagram of the eye*)

Ciliary Muscle- a band of muscle and fibers that are attached to the lens that controls the shape of the lens and allows the lens to accommodate (change focus).

Comprehensive eye exam- A comprehensive eye examination should include the testing of the following visual skills which are aspects of normal, healthy vision (see below)

Acuity-Distance visual acuity (sharpness, clearness) at 20 feet distance.

Acuity-Near visual acuity for short distance (specifically, reading distance).

Focusing Skills the ability of the eyes to maintain clear vision at varying distances.

Eye Tracking and Fixation Skills the ability of the eyes to look at and accurately follow an object; this includes the ability to move the eyes across a sheet of paper while reading, etc.

Binocular fusion the ability to use both eyes together at the same time.

Stereopsis binocular depth perception.

Convergence and Eye Teaming Skills the ability of the eyes to aim, move and work as a coordinated team.

Hyperopia a refractive condition that makes it difficult to focus, especially at near viewing distances.

Color Vision the ability to differentiate colors.

Reversal Frequency confusing letters or words (b, d; p, q saw, was; etc.)

Visual Memory the ability to store and retrieve visual information.

Visual Form Discrimination the ability to determine if two shapes, colors, sizes, positions, or distances are the same or different.

Visual Motor Integration the ability to combine visual input with other sensory input (hand and body movements, balance, hearing, etc.); the ability to transform images from a vertical to a horizontal plane (such as from the blackboard to the desk surface).

Computer Vision Syndrome (CVS)- the complex of eye and vision problems related to near work that are experienced during or related to computer use. Its symptoms include eyestrain, dry or burning eyes, blurred vision, headaches, double vision, distorted color vision, and neck and backaches. The condition is caused by various internal and external factors. Treatment options may include prescription glasses and/or vision therapy.

Cone- light-sensitive retinal receptor cell that provides sharp visual acuity and color discrimination. (*see also [Rod](#)*)

Cornea- is the transparent front-most surface of the eye. Provides most of an eye's optical power.

Convergence- the ability to use both eyes as a team and to be able to turn the eyes inward to maintain single vision up close.

Depth Perception- the ability to judge relative distances of objects. (*See [Stereopsis](#)*)

Diabetic retinopathy - Leaking of retinal blood vessels in advanced or long-term diabetes, affecting the macula or retina. Vision can be seriously distorted or blurred.

Diopter (D)- a measurement of the refractive (light bending) power of a lens or a prism (pd). The strength of prescription glasses and contacts are measured in these units. For example a lens that is 0.50 diopter (D) is very weak, where as a lens that is 10.0 diopter (D) is very strong. Eyecare practitioners use it in eyeglass and contact lens prescriptions. A negative number refers to nearsightedness, while a positive number refers to farsightedness. For example, someone with -8.00 diopter lenses is very nearsighted, while someone with +0.75 diopter lenses is only slightly farsighted.

Diplopia- double vision.

Distance Acuity- the eye's ability to distinguish an object's shape and details at a far distance such as 20

Divergence- the ability to use both eyes as a team and be able to turn the eyes out toward a far object.

Dominant Eye- the eye that "leads" it partner during eye movements. Humans also have dominant hand, foot, eye, and side of the brain (not necessarily all on the same side).

Duction Test- a test of the eye's ability to turn inward or outward while maintaining single, binocular vision with the gradual introduction of progressively stronger base-in or base-out prisms.

Dyslexia- a learning disability in which a person has difficulty with letter or word recognition. Children often are of normal or above normal intelligence; however, they have difficulty reading and sometimes naming pictures of objects. This is caused by an inability of the brain's language centers to decode print or phonetically make the connection between the word's written symbols and their appropriate sounds. This is not caused by a vision disorder. Dyslexia cannot be cured and will never be outgrown. Appropriate teaching methods can be taught to help those with dyslexia overcome their weakness by using their strengths.

Emmetropia- normal vision, no correction needed

Extraocular Muscles- six muscles that move one eyeball, includes lateral rectus, medial rectus, superior oblique, inferior oblique, superior rectus, and inferior rectus.

Eye Hand Coordination- the ability of our eyes to guide our hands, also called visual motor integration.

Facility of Accommodation- a measure of the ease and speed of the eye(s) to change focus

Floaters Small specks that pass across your field of vision, these are clumps of cells inside the transparent gel filling the eyeball in front of the retina.

Focusing skills the ability of the eyes to maintain clear vision at varying distances

Fovea- center of the retina that can produce the sharpest eyesight. Contains a high concentration of cones and no retinal blood vessels.

Fusion- the union of images from each eye into a single image.

Glaucoma An eye disease in which the internal pressure of the eyeball increases to the point that the optic nerve can become damaged, resulting in severe vision loss and even blindness (Not correctible by the use of vision training)

Hyperopia (also known as "farsightedness") A vision condition in which distant objects are usually seen clearly, but close objects are not able to be brought into proper focus.

Iris- the colored part of the eye located between the lens and cornea; it regulates the entrance of light.

Iseikonic Lens- eyeglass lens that magnifies or minifies image size. Used for correcting image size difference between the two eyes.

Lens - The nearly spherical body in the eye that focuses light rays onto the retina. The lens itself is a multilayered structure (something like an onion). In young people it is normally perfectly clear and quite elastic. As one ages its elasticity is reduced. In fact after the age of about 45 the lens' ability to change in shape is considerably reduced. That is why people over the age of 45 almost always require glasses to read and/or to see distant objects. It is not unusual for people in their 50's and older to wear bi-focal or even tri-focal lenses.

Low vision - Also called partial sight. Sight that cannot be satisfactorily corrected with glasses, contacts, or surgery. Low vision usually results from an eye disease such as glaucoma or macular degeneration.

Lutein - An antioxidant that is found throughout the body, but is concentrated in the macula. Lutein is believed to help protect the eyes from free radical damage caused by the sun's harmful rays.

Macula- the most sensitive part of the retina that is about the size of a pinhead and is where our most detailed vision occurs.

Minus (-) Lens- concave lens, stimulates focusing and diverges light. The lens is thinner in the center than the edges. It is used in glasses or contact lenses for people who are nearsighted (myopia).

Myopia (also known as "nearsightedness") A common vision condition in which a person can see close objects clearly, but lacks the ability to see distant objects with the same clarity.

Near Point of Convergence (NPC)- the closest point at which the two eyes can maintain a single united image.

Near Point of Convergence Test- measures the patient's ability to point the eyes at an approaching object and to keep them fixed on the object as it reaches the patient's nose. Normal range is 0 to 4 inches away from the nose.

Ophthalmologist- an MD who specializes in surgery and diseases of the eye. A small number of ophthalmologists work in conjunction with vision therapists or orthoptists.

Optician- is a professional in the field of designing, finishing, fitting and dispensing of eyeglasses and contact lenses, based on an eye doctor's prescription. The optician may also dispense colored and specialty lenses for particular needs as well as low-vision aids and artificial eyes.

Optic Nerve- is a bundle of nerve fiber that connects each eye to the brain and transmits images from the retina to the brain. It is also the largest sensory nerve of the eye.

Optometrist (OD)- a health care professional who is state licensed to provide primary eye care service. These services include comprehensive eye health and vision examinations; diagnosis and treatment of eye disease and vision disorders; the detection of general health problems; the prescribing of glasses, contact lenses, low vision rehabilitation, vision therapy, and medications; the performing of certain surgical procedures; and the counseling of patients regarding their surgical alternatives and vision needs as related to their occupations, avocations and lifestyle. The optometrist has completed pre-professional undergraduate education in a college or university and four years of professional education at a college of optometry, leading to the doctor of optometry (O.D.) degree. Some optometrists complete a residency. Some optometrists are also vision therapy providers.

Orthoptics- Literally means "straightening of the eyes. It dates back to the 1850's but is limited in scope to eye-muscle training and the cosmetic straightening of the eyes. Vision training is an expansion of this. It involves the training of the eye-brain connections involved in vision also, and has progressed in this century as have advancements in the knowledge of neuroscience.

Plus (+) Lens- convex lens, relaxes focusing and converges light. The lens is thicker in the center than the

edges. It is typically used in glasses or contact lenses for people who are farsighted (hyperopia). Although it may also be prescribed for other visual conditions as well.

Polaroid Lens- a lens used in sunglasses which consists of two glass or plastic surfaces with a plastic lamination between the two surfaces, and designed to reduce reflected glare.

Presbyopia- A natural part of the aging process, it occurs when the crystalline lens of the eye loses its enough of its flexibility so that the accommodative muscles of the eye can no longer bring close objects into clear focus. Usually, it becomes noticeable when a person reaches their early to mid-forties.

Prism- a wedge-shaped piece of glass or plastic that bends light. Used to measure or treat a binocular dysfunction (eye teaming problem). Sometimes incorporated in glasses. (See "[Base-Down Prism](#)", "[Base-In Prism](#)", "[Base-Out Prism](#)", "[Base-Up Prism](#)", "Yoked Prism" (link forthcoming))

Pupil- the opening at the center of the iris of the eye. It contracts (dilates) in the dark and when the eye is focused on a distant object. It opens and closes to regulate the amount of light the retina receives.

Pursuit Test- measures the eyes ability to follow a moving target.

Refractive Error- condition in which parallel rays of light are not brought to a focus upon the retina because of a defect in shape of the eyeball or in refracting media of the eye. Also called ametropia. Results in conditions like astigmatism, hyperopia, myopia, or presbyopia.

Refractive Power- a lens' ability to bend parallel light rays into focus, as measured by power diopters. In general, the greater the curvature of a lens and the greater the difference between center thickness and edge thickness, the higher the index of refraction and the greater its refractive power. Refractive power can also refer the strength of a person's contact lenses or glasses.

Refractive Media- the parts of the eye that light travels through before being focused on the retina includes the cornea, crystalline lens, aqueous, and vitreous. (*See diagram of the eye*)

Retina- the innermost layer of the eye, a neurological tissue, which receives light rays focused on it by the lens. This tissue contains receptor cells (rods and cones) that send electrical impulses to the brain via the optic nerve when the light rays are present.

Rod- light-sensitive retinal receptor cell that works at low light levels (night vision). A normal retina contains 150 million rods.

Saccades Dysfunction- a condition in which the individual's ability to scan along a printed page and move his eyes from point to point is inadequate. Symptoms include frequent loss of place while reading, skip or transpose words, and have difficulty comprehending because of an inaccurate eye movement. Vision therapy is an effective treatment option.

Sclera- the white protective covering of the eye

Stereopsis The product of good binocular vision, where the separate images from the two eyes are combined successfully into one three-dimensional image.

Strabismus (also known as crossed eyes, wall-eyes, or wandering eyes) A visual defect in which the two eyes point in different directions. In some cases these eye misalignments are not obvious to an untrained observer. One eye may turn either up down, in, or out, while the other points straight ahead. The result of this condition is a partial or total loss of stereo and binocular depth perception.

20/20 -the expression for normal eyesight (or 6/6 in countries where metric measurements are used). This notation is expressed as a fraction. The numerator (1st number) refers to the distance you were from the test chart, which is usually 20 feet. The denominator (2nd number) denotes the distance at which a person with normal eyesight could read the line with the smallest letters that you could correctly read. For example, if your visual acuity is 20/100 that means that the line you correctly read at 20 feet could be read by a person with normal vision at 100 feet. The Snellen chart is used to test visual acuity (sharpness of eyesight). This chart contains rows of letters, numbers, or symbols in standardized graded sizes, with a designated distance at which each row should be legible to a normal eye. The Snellen letter is constructed so as to subtend an angle of 5 minutes of arc (5/60ths of a degree) at a specified distance from the eye. Each portion of the letter subtends an angle of 1 minute of arc (1/60th of a degree).

Vergence- to turn the eyes horizontally (convergence- inward or divergence- outward). Accommodative vergence, fusional vergence, proximal vergence, and tonic vergence are needed to maintain single vision.

Vergence Facility- a measure of the ease and speed of the eyes to change from a converging to diverging position.

Visual Field- the total area that can be seen while looking straight ahead. (See "Tunnel Vision" (link forthcoming).) (Note Perimetry is the method of testing an eye's field of vision.)

Visual-Motor Integration (VMI)- after visual data is gathered, it is processed and combined in the brain with information from movement (eye hand coordination).

Visual-Motor Skills- the ability of our eyes to guide our hands (eye hand coordination, visual-motor integration).

Visual Pathway- route of the nerve impulses from the retina along the optic nerve, and optic nerve radiations to the brain's sensory cortex that is located at the base of the skull.

Some Books For Everyone (See also the websites re Literature)

Cva Classroom Visual Activities A Manual to Enhance the Development of Visual Skills By Regina G. Richards. Classroom activities for all ages to help develop visual skills. Objectives, success criteria and detailed instructions are included for each activity in this book. Ideal for educators.

Developing Your Child for Success By Kenneth A. Lane, O.D. Designed to help children avoid early school failure. The first few chapters discuss the many factors involved in the reading process. The majority of the book is devoted to over 630 activities that will help give children the necessary perceptual-motor skills needed to succeed in school. Activities are divided into eight categories, including visual-motor, ocular motor, laterality, sequential processing, and more.

Eye Q and the Efficient Learner By James A. Kimple. Written by an educator who is also the father of four children with learning difficulties, this book discusses the nature of visual development and the importance of the visual system to school success. Includes sections on the role of the school and the unfortunate labels that are placed on children who are having trouble; the behavioral optometry approach to helping to solve learning-related vision problems, including a "red flags" list of symptoms; some basic common sense parenting tips; and an illustrated section of home and school activities, games and exercises to enhance functioning in specific areas. Recommended for parents and educators.

Eyes on Track A Hands on Guide to Improve Students' Eye Tracking & Vision By Kristy M. Remick, O.D., Carol A. Stroud, B.S. and Vicki Bedes, O.V.T., Vision Therapist. This book is an educator's guide to improve students' eye tracking and vision perception for grades 1-6. Contains 60 pages of eye games to improve eye tracking and vision perception skills.

Pro's Edge Vision Training for Golf By Lawrence D. Lampert, O.D. Learn the hottest techniques available to take strokes off your golf game!

Seeing Is Achieving Improve Your Child's Chances for Success By Donald J. Getz, O.D. This practical guide is written in a simple and straightforward style. The author explains why kids with "good eyesight" can still have poorly developed vision and perception, and how you as a parent or teacher can spot the telltale signs. This book gives case histories of typical childhood vision problems, and how they have been helped with vision therapy. Book includes home activities.

Smart Medicine for Your Eyes; A Guide to Safe and Effective Relief from the Most Common Eye Problems By Dr. Jeffrey Ansel, O.D. Covers basic eye care, eye disorders, and treatments including information on vision therapy. Laypersons won't find the book hard to follow; it is written in a way that is easy to understand.

Thinking Goes to School Piaget's Theory in Practice with Additional Thoughts By Hans G. Furth and

Harry Wachs, O.D. Discusses Piaget's theory of intellectual development. Contains illustrated activities and strategies to help a child develop to his full potential.

UNDERSTANDING AND MANAGING VISION DEFICITS A GUIDE FOR OCCUPATIONAL THERAPISTS By Mitchell Scheiman, O.D. Written for occupational therapists to gain knowledge about vision, screening for vision problems, vision problems associated with learning disorders, brain injury, and developmental and sensory disabilities.

Visual Ergonomics in the WorkPlace By Jeffrey Ansel, O.D. This book is a must for any one who spends time on a computer.

When Your Child Struggles The Myths of 20/20 Vision What Every Parent Needs to Know By David Cook, O.D. Written for parents about their children's vision, how to detect if their child is struggling unnecessarily and where to turn for help. Included are sections on understanding 20/20 vision, visual abilities and how to find help. The author uses case histories to illustrate the various vision disorders described in the book. In addition to these sections, the author lists research on vision and vision therapy, additional reading and a glossary of terms.

APPENDIX C: MEDICATIONS WHICH AFFECT THE VISUAL APPARATUS

Drugs Which Can Affect Near Vision A Useful List

Joanne L. Smith B.Sc., Ph.Phm.*

J. Raymond Buncic, M.D., F.R.C.S.(C)t

ABSTRACT

This paper documents a list of drugs that cause problems with near vision, by virtue of effects on accommodation, occasionally refractive error and diplopia. It is meant as a reference aid to the clinician when confronted with problems of focusing on near objects or print. There are many drugs that have been reported to interfere with near or reading vision, producing blurring, decreased accommodation and diplopia. This paper lists the drugs that have been reported in the literature to produce symptoms which interfere with near vision. Case reports for the listed drugs vary greatly from many to few. The drugs have been divided into the following categories those causing (A) blurring at near, (B) diplopia and (C) induced myopia. Those drugs which only rarely cause these symptoms have been omitted.

Myopia: An example of how an uncertain medical theory leads to public ignorance, and industry capitalisation

by *Peter Pullicino*

(Diagram showing the similarity in optics of an eye and a camera)

Peter Pullicino,
Undergraduate BA/LLB,
Australian National University, Canberra, Australia

The years preceding and immediately following the Revolution saw the birth of two great myths with opposing themes and polarities: the myth of a nationalized medical profession, organized like the clergy, and invested, at the level of man's bodily health, with powers similar to those exercised by the clergy over men's souls; and the myth of a total disappearance of disease in an untroubled, dispassionate society restored to its original state of health. [\[1\]](#)

--- Michel Foucault, 1963, *The Birth of The Clinic: The Archaeology of Medical Perception.*

Thank you to Ellen Davis for proof-reading my final drafts. Thank you to the staff at the Sydney Eye Hospital Library, staff of the Canberra Hospital Library and the staff of the Library of Medical Sciences at the John Curtin Research School. Thanks to my lecturer Dr. Thomas Faunce (unit: "Health Law and Ethics") giving me a chance to write something which I've been yearning to write. Credit goes to Julian Henschke in helping me analyse my survey results and his long conversations with me on the subject. Thanks to Alex Eulenberg ("The Case for the Prevention of Myopia" [\[2\]](#) which he prepared for his undergrad in biology in 1996 under David Goss) who read drafts who was influential in starting me thinking about writing. Thanks to Thomas Quakenbush for the frontispiece graphic. Thanks also to the people who participated in my study.

Foreword by the Author

A foreword is necessary to explain why this essay came into being, and the motivations which surround its conception. Thousands of researchers publish papers each year without ever revealing why their paper was written, or whether the subject interested them, and if so, in which way. In contrast, I want to start by saying that I am suffer from myopia and that therefore the finding of a cure, or at least stopping a further progression of myopia, is a subject which is important to me.

I first was prescribed glasses when I came to Canberra from Melbourne. I was then 14 years old. The prescription was very weak. If I remember correctly it was something like RE $-0.25D$ LE $-0.5D$. [\[3\]](#) From then on my myopia got steadily worse and worse until two years ago and around three or four more prescriptions later I had RE $-1.75D$ LE $-2.25D$. At that stage it was becoming necessary to wear glasses for reading, but I resisted this instinctively. I also began to wear my glasses almost full time. The time came during my law exams in 1999 when I couldn't see the print of a book on my lap. I was on the verge of going to get my glasses re-ordered and I knew I was going to have to start reading with them.

I resisted as long as I could, and I am now grateful I did, because on the 4th of November I read something on the internet which was to change my life — a summary of Dr. Bates' [\[4\]](#) methods for improving eyesight. I stopped using my glasses, except for driving, and started palming [\[5\]](#) and sunning [\[6\]](#). I also started reading everything I could find on the method. Luckily after exams I went overseas for two months where I practiced the techniques occasionally, especially with an emphasis on taking walks and looking into the distance. I avoided most contact with computers and books, so I was only doing around two hours of near work a day (rather than seven or eight). When I returned from my stay abroad I went to visit my optometrist who prescribed RE -1.50 LE -2.00 , an improvement of a quarter of a diopter. I was very glad to have an improvement instead of having to get a stronger pair of glasses.

Three months on from my last test, full of encouragement, I am now getting flashes of clear vision at 20/40 [6/12] [\[7\]](#) (in semi-darkness) upto 20/20 [6/6] in bright sunlight. These last for very short periods of time, but the periods are getting longer and longer as I gain more control over the sensation. I can now control something in my eyes so that at will I can go from 20/100 [6/30] to 20/30, and the results are absolutely amazing for something who has had to live in a blur most of their life. My far point is also constantly being extended, so that now I can see acorns on the ground as I walk to my bus stop. When I first started Bates' method I used to use the 3rd row at movie theatres as a maximum, currently I can sit in the 15th or 20th row without discomfort.

Progress has been slow and tedious but the results have been worth my time and effort. I am now in the process of trying to understand more and more about my eyes, and how I was prevented from exploring natural therapies. In this particular essay I have tried to use mainstream journals (where possible) to back up my points, as quoting natural vision therapists would become a matter of "preaching to the converted". However I owe a great debt to those people who have paved the way for a more holistic analysis of this area of medicine.

Peter Pullicino, Canberra, May 2000

[An Inadequate Theory](#)

[Von Helmholtz's Theory Inadequate](#)

It is a rule in all scientific endeavour that if a fact is not in concord with a hypothesis then then it is insufficient, and another hypothesis must be found which better suits the facts. Unfortunately this has not been the case when it comes to explaining how accommodation occurs. Accommodation is the process that occurs when an eye focuses on objects of different distances.

The first experiment on accommodation was performed by Von Helmholtz in 1856 using a candle and observing the images that were reflected back from the cornea, lens and retina. He thought he saw the image on the lens become smaller when accommodation occurred at the near-point and hence concluded that the lens must be changing its shape, and that it is the ciliary muscle which controls the process of accommodation. This hypothesis still serves ophthalmologists up to the present day. It has gained status as a time-honoured principle.

As sacred as it may be it must be overturned. For over a hundred years, ever since cataract surgery has been performed, there have been men and women who have been accommodating without the use of a lens (aphakia), or with a hard plastic lens (pseudophakia) ^[8]. Thousands of these operations are performed each year, and a significant amount of patients regain the power of accommodation, some just days after the operation. How the ciliary muscle is acting on an artificial or no lens at all (!) is unclear.

"Fuchs (who is quoted merely as familiar example of accepted teaching) says that mechanism of accommodation "depends upon the elasticity of the lens". If this is true then no lens, no accommodation. He also says "The aphakic eye, moreover, is destitute of accommodation. The eye is incapable of altering its refractive state". The last statement is of course, not universally true, as there are cases on record of aphakic eyes that could alter the refractive state. ^[9]

[The Theories of Myopiagenesis: All Found Insufficient](#)

The cause of myopia has troubled medical science since its alarming rise following the increase of civilisation. It is somehow poetic that the further humankind has separated itself from nature the less he is capable of appreciating it.

James Ware as early as 1812 claimed that amongst 10,000 British Guardsmen not a dozen had been rejected for military service for short-sight in the space of 20 years whereas in one college in Oxford 32 out of 127 students were found to be myopic.^[10]

Such statements litter ophthalmological journals up to this day. They are indeed worrying. The University of Singapore has 65% of its graduate population myopic.^[11] My study of Australian National University students (see Appendix A), confirmed that there are significant levels here also (29%).

There are four main theories to explain the cause of myopia. These are the genetic theory,^[12] nutritional theory,^[13] the close-work theory,^[14] and the strain theory.^[15] They are all inadequate in some respects. It is not inside the scope of this essay to refute the various theories, as they all have very influential and knowledgeable adherents, and there is ample source material to verify the nature of their weaknesses and strengths.^[16] The "nature v. nurture" debate rages in journals up to the present day.

A brief survey of ophthalmic literature suggests that the number of published articles on the topic of myopia development must be in the thousands.^[17]

The most convincing theories are hybrid theories between genetic/close-work, and close-work/strain. These are, however, impractical to study because they involve too many uncontrolled variables. The debate is reminiscent of the incessant discussions about the cause of cancer, fluoridation of water and the harmful effects of mobile phones, where every writer simply quotes her/his favourite study.

The most convincing reviews simply acknowledge that there is confusion in this area.^[18] It remains to be seen whether any theory will eventually win out, and it will probably be phrased in a hybrid form anyway.

[The Professionals](#)

[Traditional Forms of Treatment of Myopia](#)

The lack of an adequate and established theory has given rise to the two main forms of 'treating' myopia which are based on mechanical solutions to do with bending light before it reaches the internal eye. Because these treatments are only concerned with a mechanical solution, the eye is viewed as an mechanical focussing system rather than a muscular system. The result is effective temporary treatments, but with long term anomalies because of the imprecise technology. The third traditional way, but by far the most unpopular, is behavioural optometry, a science which has the reputation of being primarily interested in the eye problems of children ("lazy eye", "squint"). This third way is the more natural and holistic because it is based upon muscular rehabilitation and re-coordination.^[19]

[Glasses/Contacts](#)

Glasses and contacts are now standard to treat the symptoms of myopia and have a long history dating back to the mediaeval times. They have never been tested by any government body as a method for treating myopia. This is because they are very effective, relatively cheap, and have been socially accepted for centuries. The risks are never mentioned, and anecdotes prevail. Some of these are "the more you wear glasses the worse your sight gets", to the standard "give yourself a few days until you get used to them" delivered by optical dispensers.

It is plain that if the human body is forced to receive information through a medium it will adapt itself to this medium. Glasses can never be made perfectly in shape, size, and focussing power^[20] and the resulting degeneration is known to practicing optometrists as well as anecdotally. One optometrist wrote,

One of my clearest impressions in handling myopia cases is that almost all cases of stationary myopia consist of young people who refuse to wear their correction except for those occasions that make a positive demand for normal vision. Conversely, almost all cases of progressive myopia appear to be individuals who adhere most faithfully to

Myopia theory, ignorance, industry capitalisation

the principle that their corrections must be worn constantly. From a clinical point of view, the conclusion would seem inescapable that minus lenses are an important factor among the causes of progressive myopia.^[21]

And consider the following from another optometrist,

In 1914, when the state of Maryland secured its optometry law, a clause was inserted to the effect that optometrists could not prescribe minus lenses to children under 15 years of age "except on an order or advice from a physician." In 1938, Neville Schuller, vision specialist of Toronto, Canada, stated, "I would like to have a law established forbidding the prescribing of minus glasses without extenuating circumstances. O.D. Rasmussen, O.D., Kent England, stated in his book, "Myopia, in more than ninety-five percent of cases, begins between five and ten years of age. It increases largely because the myopic eye is given distance lenses for reading." C.P. Rakusen, O.D., Shanghai, China, said, "from my experience in this land of myopes (i.e. China) I have formed strong prejudices against the evil of weak minus prescriptions in all ages." Samuel Druker of Brooklyn, N.Y., in the *Optical Journal* of March 15, 1946, wrote, "The suspicion began to dawn on me slowly that among the causes of progressive myopia it might be necessary to list concave lenses themselves. From many articles that have appeared in the past on the subject of 'Optical Poison,' a familiar term a decade ago, many other optometrists appear to have the same idea."^[22]

It is more or less the rule in Australia that optometrists and vendors of glasses work side by side, often within the same office. The financial incentive to prescribe glasses is strong, even in the light of very strong anecdotal evidence that ultimately glasses may cause further myopic progression. The medical literature denies that full-correction harms the eyes and suggests that it may 'relax' them. There is no scientific evidence to uphold the claim that correction improves the eyes^[23] and there is plenty of evidence that it may actually harm them. It is common sense that placing a piece of glass between a patient and his/her world will affect the image on the retina and how the brain adapts to see this image,

A full correction for myopia, whether a minus lens in an eyeglass or a contact lens, causes near objects focus behind the retina. ^[24]

Corrective lenses, especially contacts, freeze our eyes into a fixed focus which is applied to every visual task - a focus determined by our worst-case visual need.^[25]

The wearing of spectacles confines the eyes to a state of rigid and unvarying structural immobility.^[26]

One cannot see through them unless one produces the degree of error they are designed to correct.^[27]

The profession "optometrist" exists because the procedure of prescription does not cater for any kind of examination of the real problems which would normally be relegated to proper medical practitioner. To a person on the street the face of "eye health" is the numerous optometrists who are scattered in malls and shopping centres. Consultations are usually fifteen minutes long, and patients are only given two options once diagnosed with an error: glasses or contacts. If glasses are not the fix-all that optometry would have us believe then some big structural changes have to be made to ensure that a more holistic approach is adopted.

Optometrists are mostly free to do as they like because they cannot harm a person's eyes in the same way as a surgeon can with a scalpel. One optometrist suggested that the problem with my eyes was a 'flattening of the cornea'. Another optometrist, with myself as his last patient for the day failed to give a subjective examination and relied solely on his autorefractoscope, the result being that he increased spherical diopters unnecessarily and missed the astigmatism in my left eye. Any slackening of the standard of care is very hard to pick up or prove. The mis-prescription of glasses, even negligently, is hardly actionable due to problems with causation. The eye will adapt itself to the medium it is looking through in a matter of a few hours, if not minutes. Thus is a person who needs a —2D prescription is mistakenly given a —3D prescription and told to "get used to it" then he/she will either reject the glasses^[28] or his/her eyes will come to suit —3D, more often the latter. Because of the cost of glasses, upwards of \$60, it is most probably the case that people put up with mistakes in prescription until their body adjusts. Sudden blindness never results, objects become sharper, and genetic theories are given to explain away the increasing myopia.^[29]

There are optometrists exist who are open-minded^[30] to lens-free approaches, which is a positive sign. Jacob Liberman thinks that, at least in the USA, "the profession now seems to be on the verge of a major shift as more and more practitioners are beginning to recognise the benefits of a holistic perspective." I would not be so jubilant at this stage.

Laser Surgery in the ACT

Most laser surgery clinics because of their profitability and the elective nature of the surgery offer a free consultation in order to draw clients. I went to a consultation at a branch of the Canberra Eye Hospital, the only clinic of its kind in my area. There are three doctors at this clinic, and they are not present during the initial consultation. I was seen by an orthoptician, an optometrist who specialises in the musculature of the eye. In the consultation room there was one large picture of an eye which was anatomically incorrect, the cornea and pupil occupying a much too large portion of the spherical surface. Furthermore the curvature was emphasised to an almost ridiculous degree. In the information brochure this is how describe the condition of myopia

The short-sighted cornea is too curved, i.e. too powerful a lens for the length of the eye. The laser reshapes the curve, flattening it centrally to reduce the focus power of the eye.^[32]

This is an incorrect statement, as any ophthalmological textbook on the subject will verify. Almost unilaterally axial elongation (often coupled with corneal steepening) is the physiological cause of the blurred image that falls on the retina.

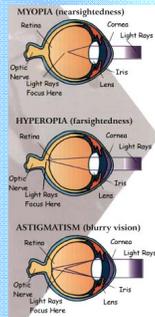

This stated by the standard textbook on correction in the field, Duke Elder's "Practice of Refraction",

In the great majority of cases, certainly in higher degrees, myopia is axial, that is due to an increase in the antero-posterior diameter of the eye... an increased curvature of the cornea not infrequently occurs, but it usually evident as an astigmatic not a spherical error ^[33]

Other studies^[34] have been more vehement,

... when myopia progresses with time, the progression is due to an increase in axial length not compensated by an increase in lens power We conclude that *all* myopia is axial in origin ^[35]

This practice of ignoring axial elongation also evident on websites of refractive surgeons in the USA ^[36] take for instance a picture from <http://www.lalask.com> (the website for a surgery in Los Angeles),

In a general sense, it is quite clear that the impression any reasonable person would come away with as to the condition of their eyes would be false. As the Australian High Court said in *Rogers v. Whitaker*, "the choice is, in reality, meaningless unless it is made on the basis of relevant information and advice."^[37]

Furthermore, on testing my vision with an autorefractoscope the orthoptician said my right eye was —2D and my left —3D, overshooting my error by around 1D in my left eye and 0.5D in my right. Hopefully once the patient has paid some money and had the follow up consultation these technical points would be considered more finely. It is interesting to note that —3D puts me in a more suitable group for laser correction, and thus more likely to consider going into the next level of consultation.

If misinformation or biased information is given at a preliminary stage in order to get a patient to pay for a more thorough examination (by which time most would be committed to going ahead) then even if the information is corrected at a later stage, we may be able to say that although the patient has been given correct information, he or she has been given two sets of information or impressions which a contradictory. This contradictory stance from the same clinic may well suffice for a civil action based on lack of true consent.

The consent form I was given thoroughly covers the common complaints of post-operative patients.^[38] Risks were disclosed at being well under 1%, although they were not named verbally, and I was referred to the consent form for the specific itemisation. The figure attached to risks was much higher than I expected, most laser surgery advertisements not venturing below 1/500 chance of complications. According to the Melbourne Excimer Laser group the procedure is "extremely safe."^[39]

Litigation becomes an option when complications surface this irreversible procedure and the patient realises that he was the "one" in "one-in-a-thousand", and that possibly the risks were too high, or that the statistics did not make sense at the time. That is a risk with all elective surgery which is portrayed as relatively risk-free. Hence we can expect to see more and more litigation in this field.

Myopia theory, ignorance, industry capitalisation

"I'm getting more calls from people looking for expert witnesses," said Ron Link, executive director of Surgical Eyes, a group that helps refractive surgery patients with problems.... Robert M. Portman, JD, legal counsel to ASCRS, said he does not know how many lawsuits have been filed regarding LASIK but that the is likely to rise with the procedure's increasing popularity. With media attention and "a lot of pretty aggressive claims" come higher expectations, he said.....^[40]

A ground for litigation may not only be disclosure of risk, but consent. As suggested above, the patient must be given appropriate understanding of the nature of his/her problem in order to consent to appropriate treatment.

A Behavioural Optometrist in the ACT

There are less behavioural optometrists in the ACT than there are laser surgeons. The title derives from a further study in a masters once the degree of optometry has been completed. Many behavioural optometrists practice standard optometry (in order to make a living), but are very valuable people because they take more time over their patients and are aware of more problems and how to correct them. Patients need to be motivated to undertake any course of muscular retraining and so this avenue is unpopular. As part of the research for this essay I went to see a behavioural optometrist and was delighted to hear her mention such words as convergence and dominance. The exercise sheet which she gave me (which was pre-printed) mentioned concepts such as "diplopia."^[41] It was a good feeling not to be patronised, but to have the accurate terms used. The use of terminology gives the patient scope to consult with the doctor and get interested in her/his problem. Her session lasted 45 minutes and was informative and constructive.

The Public

The Words Used in Connection With Myopia

The word used to describe myopia is "short-sightedness." It is one of those strange medical anomalies where the disease is actually given a positive meaning. The word covers up what actually has been lost, which is the ability to see in the distance. The sufferer has always had their shortsighted vision, so it doesn't make sense to call them "short-sighted." It's like someone who has a tumour growing out of their neck "big-necked." It is the language of incapacity and complacency. It really should be called "long-blindness," if the colloquialism is to be used. There is a strong case for always using the correct medical term in order to allow patients and potential sufferers access to information, if they choose to learn about their disease themselves. This is not my experience. "Myopia" has never been mentioned to me by anybody in the institutionalised eye-care profession.

The results of study also showed that 10% of myopic respondents identified their condition as "myopia". (See below)

Legal Treatment of Myopia in Australia

A very interesting decision is the Administrative Appeals Tribunal decision *Re: Leslie Theresa Smith*.^[42] Mrs. Smith was claiming her right to an invalid pension for blindness from the Department of Social Security. The issue here at stake was whether a high degree of myopia could classify as "permanent blindness" for the purposes of the act. It was previously resolved that one did not have to be totally blind in order to receive the pension.^[43]

Mrs. Smith had started off with glasses at age 19. At age 38 she had her right eyeball removed due to cancer. When she made her claim she said that her myopia in her left eye was so bad that she could not see faces, was scared to leave the house and often cut herself on crockery and glass. She said she could no longer drive a car. This was confirmed by family and friends.

An expert witness, Dr Hughes, an ophthalmologist, admitted that her vision was "terrible," and that without spectacles she was "as blind as a bat." While he admitted this the ophthalmologist gave evidence in favour of the Department of Social Security by mentioning her ability to read up close,

Her department within my surgery - her ability to move about without any observed difficulties as well as her ability (albeit with glasses) to read small print are all evidence that her condition makes her ineligible to qualify for the blind pension.

The doctor suggested that "blindness" should be tested with glasses on, as opposed to a person in their natural state.

Dr. Delaney, another expert, then gave evidence to the effect that Mrs. Smith's vision had decreased by 65% (corrected) or 85% (unaided).^[44] The AAT then considered what measurement should be used, corrected or uncorrected. They relied on the first ophthalmologist's evidence that with suitable glasses the applicant could read newspaper print and that she "moves around happily, bumps into nothing, pops into the room and out without any trouble." Mrs. Smith was therefore unable to claim the disability pension even though her myopia rendered her incapable for most kinds of work.

Speaking sociologically this decision highlights community attitudes towards spectacles and how myopia can affect someone's life without being recognised as a severe enough disability to receive a pension.

Scepticism About Natural Methods

The most famous book on vision improvement is Aldous Huxley's "The Art of Seeing" (London,Chatto And Windus, 1943) which was published in 1943. This was a time when the drive for more visual acuity was at a peak because of the need for fighter pilots and entry into various forms of military training. The largest and most useful (in my opinion) is Bates' system and this was the subject of Huxley's book. As public interest in natural methods increased the institutional journals were forced to respond. Some contributors were generally positive about finding a place for Bates' system in their existing practices.^[45]

A final word. At odd times I was induced by force of necessity to try some of Dr. Bates's work, and I must say that though the instances tried were few and the treatment short and casual, I was impressed with some potentialities of the method, not as a cure-all, but as an adjuvant to the correction of visual errors. The establishment of a research centre on this work at some university eye clinic... is I believe the only way to meet Mr.Huxley's dissertation.^[46]

Generally speaking these open-minded scientists were out numbered. In the next issue Pascal was reprimanded by W.H. Crisp in an article which was given three times more space. Crisp ends on a cautionary note by quoting Duke-Elder, possibly the most famous ophthalmologist of last century,

[Bates' method] may be dangerous in the hands of the impressionable who happen to suffer from glaucoma or detachment of the retina, and undoubtedly will be dangerous in the hands of the anxious parent of the myopic child... ^[47]

It is up to readers to judge for themselves what went on in the discussion which took place at the end of World War II. After the war journals regard the matter as settled in favour of the status quo. It seems that 1943 was a crucial time where natural methods could have been integrated into normal medical practice, but instead they were side-lined.^[48]

A prominent natural therapist, and one of the few recently published authors in this area, has highlighted that he does not see natural methods supplanting traditional forms of care and sees no reason why the medical profession should be so protectionist.

All of my students are, of course, advised to be under the care of an eye doctor when pathologies are present---in fact, it is a requirement.^[49]

As natural vision therapies involve no drugs or surgery their only great risk is the loss of a chance for a qualified doctor to diagnose a serious eye condition. Current optometrists have the facilities to diagnose glaucoma, whereas natural vision therapists may not have the equipment necessary. This simple fact cannot discredit their practice however.

In the light of my success with natural vision methods, and the accounts of various people around the world on newsgroups, I would strongly recommend that proper consideration be given to integrating natural techniques into the health system. One obvious problem is the cost and time that it will cost to monitor a patient's improvement and correct use of the methods. They also represent a threat to the wholesale prescription of glasses, an industry worth hundreds of billions of dollars.

My Study

As part of the research for this essay, in order to substantiate some claims made herein, I surveyed 68 students in the corrals at Chifley library on the 19th, 22nd, 23rd of April. Chifley is the central library on campus and houses most of the books for use in Humanities.

The form given to the library-users appears in the appendix. It was designed to elicit more that "yes/no" response from the sample group, but this gave rise to problems with interpretation of questions and also of unclassifiable answers. However some useful data emerged and I present it below,

Number of respondents over 30 years of age	11%
Percentage of group with refractive errors	57%
Readily identifiable as myopic from data provided	29%
	(Therefore 51% of all those with refractive error where identifiable as myopic)
Of those readily identifiable myopes how many described themselves using the term "myopic" or "myopia"	10%
Of group with refractive errors,	

Myopia theory, ignorance, industry capitalisation

Number of respondents who didn't/couldn't/wouldn't communicate their condition (eg. a typical response, "I can't see")	18%
Number of respondents with refractive error who put their error down to hereditary theories	33%
Number of respondents with refractive error who put their error down to near work	23%
Number of respondents with some knowledge of laser surgery (ie. know more about it than it just exists)	61%
Number of those respondents with knowledge of laser surgery who mentioned cost	59%
Number of those respondents with knowledge of laser surgery who mentioned risks or had an apprehension of risk	50%

The scope of the study was always limited by time and manpower, but in hindsight I wish I had managed to get a better questionnaire prepared. Also I would never have expected the range of responses - some people wrote more than the space provided for them, others just signified "no" or "yes." It is hard to get across the subjective element I feels when I look at some responses. For instance people tended to used the word "burn" when it came the laser surgery, and tended to identify the area of the eye being burnt off as the retina. Other showed good knowledge of their prescription but not their condition, or vice-versa. There is not scope, or experience on my part, to adequately explain these anomalies in the responses.

Conclusion

It is said that to become myopic has a potentially negative impact on self-esteem, career choice, and ocular health. However we have been unable to identify baseline studies which indicated whether myopes themselves feel they have a significantly impaired quality of life.^[50]

What a ludicrous statement. The researchers who wrote that should venture outside their offices every once in a while. Myopia disrupts eyesight in a massive chunk of the population, with disastrous effects on vision,

Myopia is really a disease of appalling incidence and damage, affecting in America 70 million and resulting in 12 million cataracts, 5 million detachments, macular degeneration, glaucoma etc...^[51]

The problem is severe but not critical for many sufferers because of a quick and easy means of approximate correction. Society is now so dependent on lenses, that it has given the industries which make the problem invisible the power to entrench themselves. It is unfortunate that the lucrative business of lenses and surgery is anti-thetical to any real treatment. Flintcroft in the British Journal of Ophthalmology supported this view in his commentary entitled "Ophthalmologists should consider the causes of myopia and not simple treat its consequences,"^[52]

Whilst is certain that refractive surgery will play a major role in the ophthalmological management of myopia in the future, ophthalmologists should also take up the challenge of preventing or curing myopia by addressing the cause and not simply treating the consequences

Not only must we call for some real scientific endeavour in this field, first to discover an accurate model of accommodation and secondly in the aetiology of the disease, but also for more information to be given to the public. It seems that either the medical profession must admit its uncertainty, or else transmit it in the form of ignorance. At the ground level people are being prevented from exploring other treatments because of an inherent lack of knowledge coupled with an assumption that the medical authorities have a viable scientific theory. They do not, and admission of this lack scientific consensus is essential for the patient to understand the basis of knowledge on which the treatment he/she is being given.

The majority of patients who receive treatment do not even know what their condition is called. The doctrine of informed consent and disclosure of material risks is a farce when the patient does not even know what is wrong with his or her eye. To understand what the treatment is going to do to one's body one must first understand what it aims to cure. This becomes fundamental when something as precious as eyesight is being discussed.

Natural solutions should be considered and should always be suggested where the patient has been undertaking some activity which could result in degeneration of the muscles (i.e., Extensive unbroken periods near-work etc...). Natural vision teachers should not be allowed to suffer the same discrimination that the chiropractic profession had to face for many years because of its threat to established medical practice. ^[53]

In conclusion, it is well to remember that in history many different things have been undisputed medical practice which to later generations seem obtuse and senseless (i.e., lobotomies, shock therapy, bloodletting etc...). There is no doubt that wholesale dispensation of glasses and laser surgery will one day take their place in that list. Nobody is content with the current state of affairs except the money-makers.

This book gives a good account of the antitrust litigation.

APPENDIX A

Response Form for Study on Attitudes to Refractive Error, issued by Peter Pullicino, Undergraduate LLB/BA.

NOTE: All responses are **confidential** and are part of personal research into my essay for "Health Law and Ethics" a unit run by Dr. Thomas Faunce. I must state that no university body is funding this study, and the research is not affiliated to the ANU; it is my own.

I. Age (circle) 1-10, 11-20, 20-29, 30+

II. Occupation: _____

III. Number of years you have spent in educational institutions (in any capacity): _____

1. Do you need prescription glasses/contacts? Y N Possibly

2. Do you wear prescription glasses/contacts? Y N

(if No to both then jump to question 13)

4. Do you know what strength your prescription glasses/contacts are?

Right Eye, _____ Left Eye _____
(if you don't know exactly maybe you would like to comment: _____)

5. How long have you worn prescription glasses/contacts? _____

6. How many hours a day do you wear them? _____

7. How many hours do you spend on average reading or in front of a computer? ____

8. Can you live your life without them? How hard would it be to get through your average day without them on this scale

No Problem // Easy // Not without difficulty // Hard // Impossible

9. If you have glasses or contacts, do you like to wear them (e.g., In a fashion sense, tinted lenses etc....)?

10. Why do you wear prescription glasses/contacts, for what condition?

11. Do you know/suspect what caused your need for your corrective lenses?

12. Have you considered the option of laser eye surgery (LASIK etc...)? What has prevented you from following up this option?

13. Do you know anything about laser eye surgery (for instance cost, what change it makes to your eye's anatomy etc...)?

if you know of any risks, list them according to gravity,

In the days before today's eyecare practitioners went to medical and optometry school, there were a number of brave doctors of optometry who stepped up and challenged the myth that glasses don't make myopia worse. Here are a few excerpts. --Alex

S. Drucker, O.D. *Optical Journal-Review*, March 15, 1946:

One of my clearest impressions in handling myopia cases is that almost all cases of stationary myopia consist of young people who refuse to wear their correction except for those occasions that make a positive demand for normal vision. Conversely, almost all cases of progressive myopia appear to be individuals who adhere most faithfully to the principle that their corrections must be worn constantly. From a clinical point of view, the conclusion would seem inescapable that minus lenses are an important factor among the causes of progressive myopia.

OPTICAL POISON

From *Spectacle Hobby* by Jacob Raphaelson, OD, 1961:

The bad effects of minus lenses on vision and health have been recognized by many optical men in earlier years, in this and other countries. There have been many voices raised against the promiscuous use of minus glasses at the beginning of th century, and a few feeble voices were heard up to the decade of 1950. In the decade of 1950, the fitting and wearing of minus glasses became the rule rather than the exception.

In the last century, in the land of the Tzars (Russia), minus glasses were sometimes used to evade military conscription. A few months before the appearance for army examination, the conscript went to an optical doctor and got a pair of strong minus glasses which he wore steadily until prior to the examination. He was then sure that he would be rejected on account of his vision. The minus glasses had weakened his eyes and made his distant vision very poor.

...

In 1914, when the state of Maryland secured its optometry law, a clause was inserted to the effect that optometrists could not prescribe minus lenses to children under 15 years of age "except on an order or advice from a physician." In 1938, Neville Schuller, vision specialist of Toronto, Canada, stated, "I would like to have a law established forbidding the prescribing of minus glasses without extenuating circumstances.

O.D. Rasmussen, O.D., Kent England, stated in his book, "Myopia, in more than ninety-five percent of cases, begins between five and ten years of age. It increases largely because the myopic eye is given distance lenses for reading."

C.P. Rakusen, O.D., Shanghai, China, said, "from my experience in this land of myopes (i.e. China) I have formed strong prejudices against the evil of weak minus prescriptions in all ages."

Samuel Druker of Brooklyn, N.Y., in the *Optical Journal* of March 15, 1946, wrote, "The suspicion began to dawn on me slowly that among the causes of progressive myopia it might be necessary to list concave lenses themselves. From many articles that have appeared in the past on the subject of 'Optical Poison,' a familiar term a decade ago, many other optometrists appear to have the same idea."

Joseph Kennebeck, OD (in *Why Eyeglasses are Harmful for Children and Young People*, 1969, pp. 53-54) tells how minus lenses turn functional myopia into structural myopia:

Dr. X said my patient allowed him to go over her eyes, and he reported that he found Miss Y should have minus .50 glasses, the same Rx I found but would not fit at the time, which I told Dr. X. He asked me why I would not prescribe it. I told him that Miss Y's dynamic skiametry findings were plus 2.00 [farsighted], and that I was giving her orthoptic treatment, etc.... He said with WEARING THE MINUS .50 FOR A WEEK OR TWO, THE DYNAMIC SKIAMETRY PLUS 2.00 FINDINGS WOULD BE GONE. What became of the plus 2.00 dynamic skiametry findings? Something had to take place, and change. I reasoned that this was eliminating the plus 2.00 skiametry findings, and creating a worse condition. To think that the wearing of minus .50 would do that, and it would, meaning the refractive media would have to become permanently 2 diopters more convex, and that the circular ciliary muscles would have to become stronger than they were--too strong.

Myopia: A Pernicious Bad Habit

by *Robin Parsons*

Last Revision: September 26, 2000

Myopia or shortsightedness may have been in existence for millions of years ever since the human eye as we know it today became part of the gene program which produces the entire human body. The basic optical anatomy of the eye comprises a focusing lens which can project images of objects in the visual field on to the retina. The lens has a large degree of accommodation which allows the image to fall in front of or behind the retina. This large range of accommodation allows the lens to cope with the change in size of the eyeball through natural growth and also to deal with objects at different distances from the eye. In the early years of development we learn to see at all distances, to focus accurately and to use the binocular vision afforded us by two forward facing eyes.

I do not accept that myopia is a disease or a complaint. It is merely a pernicious bad habit in the visual process, produced in the first instance by incorrect use of the eyes when reading print.

Medical Science has tried hard to identify the cause of myopia and has failed to do so. It naturally follows that attempts to prevent it and eliminate it have also been abortive. The problem is one that affects all vertical thinkers, the logical searchers for the truth. They dig a hole and when nothing is discovered they keep digging in the same hole. When a lateral thinker tackles the hole he tries for a while and then gives up. Then he goes off and digs another one!

Few inventions and discoveries are the result of logical thought. Logicians tread the same path every time with little success. Real innovations are accidents like penicillin. A cure for cancer may come about when a scientist is investigating the mating habits of the purple spotted tree frog in the Amazon jungle.

When Edward de Bono coined the term lateral thinking he might have had in mind Darwin and dare I mention his name, Dr W H Bates. Both men were well ahead of their time. It took the ideas of a nineteenth century naturalist to demolish the Garden of Eden; and an American physician to put forward new ideas on refractive errors of the human eye.

In spite of his abysmal anatomical ignorance, his unusual experiments and his wild claims of extravagant cures, Bates was right in one reasoned judgment: myopia is a self imposed condition due to incorrect use of the eyes and hence curable. I researched the problem for more than forty years, getting glimpses of

better vision which I knew were the result of variations in pupil size. Then I noticed something that Bates said. I must have read it many times without realising the significance of his seemingly casual aside. He said that the myopic eye never sees as well as the normal eye, even at the nearpoint whether or not correcting lenses are worn.

Like most myopes I could always see wonderfully well at reading distance, with or without glasses. Most traditional professional eye doctors claim that the eye is too long from front to back and the eye focuses the image of distant objects in front of the retina. They fit negative lenses to restore the image to its correct place and then assume that the eye is now normal, with a new starting point and a lens system which matches the eyeball.

When, as is almost universal the myopia becomes worse after a few years the traditionalists are rather cagey in their observations. An optician of mine said, "it tends to settle down" when I queried the decline in my vision. Does the eyeball become progressively longer? How many new starting points can the eye endure?

The extra ocular muscles are sometimes blamed for refractive errors; mysterious pressures within the eye are also suggested as the culprits. Mutant genes are said to be a possibility, and the old standby heredity has come in for a lot of stick.

I have a few ideas myself. How can I be sure that myopia has been in existence for millions of years? How could it be otherwise? Every person on the planet, if he has a flexible lens, whether normal sighted or not produces symptoms of myopia many times during the course of every day. Bates claimed he had seen it occur in so called normal eyes, ranging up to twenty dioptries of myopia. I see no reason to argue with this obvious phenomenon.

The individual who is permanently myopic cannot eliminate it until he knows how. Those with normal sight produce myopia for a fraction of a second and then return to their habitual central fixation and high speed shifting. Their activities are the result of the reflex control of the cerebellum, that part of the brain which stores and operates all learned physical actions. The golfer who persistently slices the ball is just as much a victim of his own cerebellum as is the individual with common refractive errors.

The problem where myopia is concerned is that few people seem to understand how accommodation of the eye takes place. Bates certainly had little knowledge of the subject. To his way of thinking the lens was not a factor in accommodation. Instead he adopted the long discredited hypothesis that the extra ocular muscles altered the shape of the eye. It would seem that Bates was trained in a different school from conventional medical men and with one accord his method was disregarded as quackery.

Then the charlatans in the shape of nature cure quacks saw an opportunity to make a fast buck. The gullible public were quick to rally round the new breed of conmen and the professional eyequacks were laughing all the way to the bank. They were assisted in their promotions by the obliging eye pupil which affects visual acuity by its effect on the depth of field of the lens of the eye. In bright light the pupil

contracts and tends to override several dioptres of myopia. When ambient light decreases the pupil dilates and the existing myopia lowers visual acuity considerably.

If a myope really wants to be aware of how bad his vision is without the aid of the smaller pupil, he should visit his ophthalmologist and have him put a few drops of atropine in his eyes. This happened to me recently when I had a test for glaucoma. Under the influence of atropine my pupils enlarged completely and without glasses my visual acuity was worse than I had ever known it before in my life.

Janet Goodrich, a well-known professional vision teacher was once obliged to leave Singapore after making claims of myopia cures. When challenged by the Singapore Eye Institute to substantiate her statements she found out that the doctors intended to see how her clients fared when atropine was used in their eyes. She realised that with pupils dilated her clients' visual acuity would be much reduced and declined the confrontation.

The Bates Method relies for its effect on the activity of the eye pupil. All the Bates drills, such as palming, blinking, flashing and the concentration of the mind on nearby objects in the imagination drills, encourage the contraction of the pupil. This contraction increases the depth of field of the lens and hence improves visual acuity. As it is temporary there is no permanent improvement in vision. Devout addicts of the Bates Method are mainly wishful thinkers and have only themselves to blame when their aspirations fail.

The professional eyequacks are not stupid enough to believe that they can improve myopia. What they can do is teach you how to temporarily control the pupil and affect the depth of field and visual acuity.

This is the worst scenario as portrayed by the NVI gurus. Myopia can be eliminated but not by practising a few exercises at odd times during the day. One has to attack myopia at source, enter the brain computer software and reprogram it in the cerebellum. The whole faulty visual syllabus has to be abandoned and replaced by a correct one.

The conventional experts bury themselves in laboratory experiments, mutilating baby chicks or wretched monkeys in an effort to produce some semblance of credible statistics capable of lasting a brief scrutiny by sceptical colleagues before consigning such meaningless rubbish to the trashcan.

If one requires reliable evidence regarding the prevalence of myopia it is only necessary to consult the obvious statistics which are undeniable. One out of five members of the civilised world develops permanent myopia; two out of five in Japan and China. What is most impressive is the fact that every single one of these individuals, in whatever part of the world he or she lives, develops symptoms of myopia in exactly the same way. In most cases it occurs during the early years of the learning process. There is no training required, no one needs to be shown how, no teacher to coach the method or any diploma to aim for. Unconsciously and insidiously the victim successfully acquires the establishment of long term myopia. It is as easy as falling off a log.

If it is that easy to develop, why is it so difficult to undevelop? The truth is that myopia is very easy to eliminate, always providing that elasticity remains in the lens of the eye. All that is required is to reprogram the brain computer software, the cerebellum.

This sounds like science fiction but is it really? From birth throughout life one programs and reprograms the cerebellum which controls every learned physical movement. Every time we learn a new skill it is not effective until it is installed in the cerebellum and is then used unconsciously. Every person on this planet relies on this part of the brain. Without it we should find it impossible to survive for a second without collapsing in a heap as helpless as a newborn baby kicking its limbs and howling pathetically for attention.

Vision is wholly dependent on the cerebellum. No one knows how long it takes the baby to see effectively, to focus the eyes and become part of its surroundings. We take it for granted that we can see and use our eyes to develop new skills, to become scholars, artisans, musicians, athletes or the thousands of different types of community members.

Whilst we are developing vision in early childhood we are unconsciously feeding the cerebellum with new skills. For millions of years the eye has been the foremost sense, for survival in a hostile environment. It evolved not once but at least forty or more than sixty times to produce independent prototypes. There are still about nine different types of eye in the animal kingdom; ours is the most successful in the human environment. Primitive men with less than perfect sight did not last long in an environment of sharp eyed hungry predators. There was never a surviving gene to find its way to succeeding generations. Natural selection is cruel but brutally efficient.

myopia [mì-o' pi-?], *noun* short-sightedness.

my'ope ([-op]) *noun* or
my'ops ([-ops]) a short-sighted person.

myopic ([-op']) *adjective* short-sighted (also figurative). *noun* a short-sighted person.
[Greek myops short-sighted, from myein to shut, and ops the eye]

The term myopia stems from the appearance of those individuals who screw up their eyes in an effort to see and has no reference to any other characteristic of the eye. Nowadays it is an accepted term for shortsightedness.

It has been pointed out many times by most writers on ophthalmology that although one fifth of the world suffer from established myopia, the vast majority, the four fifths of mankind go through life unscathed although they are subject to the same environmental conditions as their normal sighted brethren. Bates claimed the reason was that the minority strained and the majority did not. Some suggest that strain is caused in numerous ways, boredom, aggressive teachers, fear of failure or any one of the many distractions of the schoolroom. Bates said that relaxation was the obvious cure for myopia and

urged myopes to relax at every available opportunity by adopting various drills, both physical and mental. The results are hardly encouraging.

Lateral thinking is required in this instance. Relaxation does not necessarily improve myopia. Learning to see correctly does bring much relaxation. There is a subtle difference here. The most relaxed individuals on the planet are in churchyards and they do not see worth a damn.

I agree with Bates that strain accompanies myopia. People fail to improve their vision because they are vertical thinkers. They are conditioned to accept that myopia is a strain to see distant objects allowing them to see perfectly at the near point. The lateral thinker has realised that it is a failure to see perfectly at the nearpoint which is the CAUSE of ingrained myopia. Once this condition has been established it is not long before the myope discovers that his vision has become worse at distances beyond a few feet. At the near point he appears to see quite well and he loses interest in outdoor activities and prefers the company of books. It can be demonstrated that myopes cannot see perfectly at any point in the range of vision, whether wearing correcting lenses or not. They always focus the images of all objects in the visual field to some point in front of the retina.

With the development of the printing press the educational process really took off. The young were pressganged into schoolrooms and expected to learn or else. More and more facts were presented for consumption and time became the limiting factor for success in a developing world. To cope with the supply of information it became necessary for pupils to read faster and faster. Four fifths managed to do it the correct way; one fifth did not.

What is the difference between these two species, the myopic and the normal sighted when they both share exactly the same environment? Bates suggested that one strained to see whilst the other did not.

Few people pay much attention to their sight until they lose it. They take it for granted. I can remember the development of myopia when I was a child and today I can recall exactly how it happened. Basically it is simply a case of trying to see too much at the same time.

Let us examine the development of myopia. A lot of thinking people believe there are many different causes, some fairly tenable and others quite bizarre. I cannot accept any of these; they are far too difficult for a simple mind like mine to grasp. There are more than a billion myopes on the planet, scattered throughout the civilised world and without exception there is one cause. It has to be simple; otherwise how could it effect every nation on Earth, in exactly the same environment and conditions at roughly the same time, namely developing youth during the educational system? No one deliberately learns to be myopic; there are no courses to attend, no diplomas to aim for.

Some authorities claim that the eyeball elongates to produce myopia. There has been some experimental work on this hypothesis which has produced a few meaningless statistics which have as much relevance to myopia as one's size in shoes. It is said that measurements have been made which prove that myopes have more elongated eyeballs than the normal sighted. There may be some eyeballs which are a teeney-

weeey bit larger or smaller than others but they are equally distributed amongst the 6 billion members of the planet whatever their refractive state. How many millions have been measured anyway?

Then there is the old chestnut cited by Bates: that accommodation is controlled by the extra ocular muscles. If you believe that you will accept the fairies who live at the bottom of my garden.

I have already mentioned lateral thinking, the stuff of inventions and discoveries of all kinds. It is generally accepted that being short-sighted is a failure to see distant objects. I say it is nothing of the kind. It is the inability to see clearly and efficiently at the near point. Most myopes see well at reading distance, whether wearing glasses or not. **AT LEAST THEY THINK THEY DO.** I shall endeavour to show you the truth of my argument. I can assure you that unless you can understand me your chances of eliminating myopia are precisely nil. The vertical thinkers believe that they have to restore distant vision. Lateral thinkers know different; they have to learn to read correctly, with central fixation and ultra fast high speed shifting at the near point particularly when reading, the only way the eye has evolved to perform in conjunction with the brain computer and the cerebellum. As correct reading is established at the near point then clear distant vision returns as surely as night follows day.

To understand how and why myopia develops it is necessary to examine the way in which the eye signals information to the brain. The retina receives an image of the visual field but very little of it is processed in the brain to activate memory paths and the intelligence sector. Only a minute part of the retina, the fovea, is used for this purpose and it might be compared with the finger on the keyboard of a computer passing single units of intelligence to the software within. Our units of intelligence are nothing more than minute currents of electricity flowing in the brain as cell switches are turned on and off. As in manmade computers it is the combinations of these cell pathways, which we accept as intelligence.

Photons of light striking the cells in the retina activate them and cause them to pass tiny electric current flows to the brain. Without constant activity the retinal cells cease to pass information. A still picture on the retina is ineffective and after a second or so the eye becomes temporarily blind. The eye is in constant movement and the fovea shifts at high speed to send minute signals to the brain.

When a child first learns to read he starts with single letters. The eye traces out the shape of the letter sometimes with the aid of finger or a pointer. Each letter is recorded in the brain as a memory pathway. When this pathway is reactivated in the brain the individual recalls it as the letter so laboriously learned by continual shifting of the eye about the letter. As the letters of the alphabet are learned they are assembled to form words. To recall a memory of a word the shifting process has to be repeated in the brain letter by letter. This is a remarkably simple process but as they say, from acorns great oak trees grow. From the 26 letters of the alphabet just think of the wealth of literary knowledge which flows. And it all starts from that succession of little foveal shifts in the infant schoolroom.

We all forget the beginnings. As we progress in the educational system we read faster and faster. The foveal shifting continues at high speed up to about seventy shifts a second. At higher speeds there is a phenomenon known as persistence of vision. A flashing light which exceeds about seventy flashes a

second will be seen as a stationary light. Somewhere in the modus operandi the myope comes on stage. He tries to extend the information signalled by the fovea by including the area of the retina adjacent to the fovea. To do this he needs to slightly defocus the image so that it spreads from a sharp point of focus on the fovea to the retinal cells adjacent to it. This is achieved by a change in shape of the lens which becomes more convex. In this way the incoming image is sharply focused at a point in front of the retina and arrives at the retina out of focus. The detail of reading matter is large enough to be seen quite easily at the near point and as far as the myope is concerned he has gained an increase in reading speed. He now sees in blobs of print instead of a rapidly shifting series of minute foveal shifts, letter by letter.

The learner myope then discovers his problems at the distance where detail is so much smaller and needs the rapid foveal shifts to interpret it. His blob reading technique is now a handicap rather than an advantage. He still focuses incoming images in front of the retina. Why does he not focus the image on to the retina instead of in front of it?

It is not normally possible to voluntarily focus the lens of the eye. When one looks from point A to point B the eyes converge or diverge to direct attention to a desired spot in the field of view. This results in a change of the angle subtended by the optical axes of the eyes and it is this angle which is ganged to the focusing lens suspended in the ciliary muscle. We learn to judge distance this way as in a mechanical rangefinder. Every movement of the eyes automatically changes the focus whether we like it or not.

The problem now for the myope is this relationship between the angle subtended by the optical axes of the eyes and the focusing mechanism. When looking at distant objects the eyes are parallel. As has been said before you cannot voluntarily focus the eyes unless you move them to a state of convergence or divergence. The degree of focusing is ganged to the angle subtended by the optical axes of the eyes. If the eyes are parallel and the image is focused in front of the retina the only way the focusing can alter and project the image on to the retina is by means of diverging the eyes.

Over the course of time, the myope has developed the habit of looking at blobs of detail at all distances both near and far. His eyes are directed at the same spot in order to present a single picture to the brain. This image is slightly out of focus since the sharply defined one is registered in front of the retina. Wherever he looks there is no sharp image to interpret. At reading distance the position is exactly the same but the detail is large enough to distinguish reasonably well. Central fixation is reduced to a more or less degree and rapid shifting is also absent.

Divergence of the eyes is necessary to flatten the lens; convergence causes the lens to become more convex. When the eyes are directed to the same point of attention either movement of the eyes would immediately result in two different images being presented to the brain. Normally only one image, that of the dominant eye would be accepted. Therefore we always direct the eyes to the same point of attention in the visual field.

The myope has a dilemma wherever he looks but the serious problem becomes more apparent when he looks at a distant object. The optical axes of his eyes are parallel and any attempt to focus involves an

attempt to diverge the eyes. If successful not only would this produce a double image but in addition there would be the effort to develop a divergent squint. This will cause discomfort and pain which are the distressing symptoms experienced by all myopes when they try to perform this impossible contortion.

It follows that any conventional attempts to exercise the eyes in an effort to strengthen vision will be abortive. In addition the improvement in visual acuity produced by changes in pupil size has no effect on accommodation although those who experience such temporary effects do not understand the futility of their efforts. In spite of continual disappointments when permanent improvements in vision are not established they still persist in the same old routines prescribed by professional NVI teachers.

The fitting of negative lenses temporarily relieves the situation but almost at once the myope starts to re-establish the old accustomed habit of looking at blobs of detail. Rapid shifting of the normal sighted eye is absent through disuse. The old merry go round goes on and on. The unfortunate ones develop a very high degree of myopia which worsens until presbyopia hardens the lens and prevents further deterioration of the complaint.

The majority of myopes seem to cope adequately with negative lenses. Unconsciously they redevelop a degree of normal central fixation and shifting. Opticians are aware of the limitations of traditional treatment and will admit that myopia does not regress too much in all cases. Those that do are generally ignored as being incorrigible.

The only way to eliminate myopia is to reprogram the cerebellum, an almost impossible task for an adult who has developed myopia as a child and permanently worn glasses of increasingly powerful strength. It can be done but it needs a complete reversal of the myopic habit and the reinstallation of the correct habits of the normal eye. Every time one looks it needs to be done with central fixation accompanied by high speed shifting. How does one do this?

It is quite simple really but as Bates says, it can be exceedingly tedious in the early stages. One attends to the reading of print and practises central fixation on it, letter by letter. There will be little noticeable result for many years. Some will be more successful than others. There will be occasional flickering shifts as the eye builds up speed. Eventually it becomes possible to read with the eye shifting letter by letter. Perhaps after many years the process will become habitual. Few have the dedication to be successful.

Relearning how to read print with central fixation and rapid small scale shifting produces almost miraculous results but it can take a very long time. Once one becomes accustomed to the principle of looking at small areas in rapid succession there are little instances of success in the appearance of real vision. These will instil confidence and inspire further practice. Most convincing of all is the extraordinary relaxation which seems to involve every nerve in the body. As near vision improves so too will distance vision. Logically how could it do otherwise?

Aldous Huxley, in his book *The Art of Seeing* describes an incredibly simple little device which I found

indispensable in practising central fixation and high speed shifting when reading. It consists of a piece of black card about the size of a book page with a horizontal slot cut in the middle. The width of the slot is arbitrary; I find two or three lines about right. The card blots out much of the printed material and encourages attention to be directed to the print in the slot thus avoiding the tendency of the myope to stare.

As one progresses one becomes aware of a blackening of the print and a concentration on small areas of the print, individual letters or parts thereof. There is also a noticeable feeling of relaxation as previously mentioned.

Since the myope has been used to gobbling up whole chunks of printed material at high speed, to suggest that he slows down his reading to such an extent will hardly be easy, especially as he needs speed to cope with his job of earning a living. In time the new correct reading habit will replace the old one and reading speed with rapid shifting will gradually build up. As I emphasise, much practice is required. If it is any consolation it is the only way back to normality. There is no other way!

Perfect Sight Without Glasses

William Horatio Bates (1860-1931) first published his treatise, *The Cure of Imperfect Sight by Treatment Without Glasses* (title page), also known as *Perfect Sight Without Glasses* (cover), in 1920.

In 1943, Dr. Bates's wife Emily Bates had an abridged version of the book published under the title *Better Eyesight Without Glasses*. That book, which is still in print (by Henry Holt), omitted many experimental details, most scholarly references, and all photographs. It also omitted references to the supposed safety of looking directly at the sun (an omission that is repeated in this electronic version).

In 1978, after the copyright on the original edition had expired, [Health Research Books](#) began to sell reprints, which are still available.

Except where noted, this electronic version contains the entire text of the original edition.

- [Front Matter](#)
- [Preface](#)
- [Contents](#)
- [List of Illustrations](#)

- [Chapter I: Introductory](#) Prevalence of errors of refraction - Believed to be incurable and practically unpreventable - The eye regarded as a blunder of Nature - Facts which seem to justify this conclusion - Failure of all efforts to prevent the development of eye defects - Futility of prevailing methods of treatment - Conflict of facts with the theory of incurability of errors of refraction - These facts commonly explained away or ignored - The author unable to ignore them, or to accept current explanations - Finally forced to reject accepted theories.

- [Chapter II: Simultaneous Retinoscopy](#) Retinoscopy the source of much of the information presented in this book - What the retinoscope is - Its possibilities not realized - Commonly used only under artificial conditions - Used by the author under the conditions of life on human beings and the lower animals - Thus many new facts were discovered - Conflict of these facts with accepted theories - Resulting investigations.

- [Chapter III: Evidence for the Accepted Theory of Accommodation](#) Development of the theory - Behavior of the lens in accommodation as noted by Helmholtz - General acceptance of these observations as facts - Abandonment by Arlt of the true explanation of accommodation - Inability of Helmholtz to explain satisfactorily the supposed change of form in the lens - Question still unsettled - Apparent accommodation in lensless eyes - Curious and unscientific theories advanced

to account for it - Voluntary production of astigmatism - Impossibility of reconciling it with the theory of an inextensible eyeball.

- **Chapter IV: The Truth about Accommodation as Demonstrated by Experiments on the Eye Muscles of Fish, Cats, Dogs, Rabbits and Other Animals** Disputed function of the external muscles of the eyeball - Once regarded as possible factors in accommodation - This idea dismissed after supposed demonstration that accommodation depends upon the lens - Author's experiments demonstrate that accommodation depends wholly upon these muscles - Accommodation prevented and produced at will by their manipulation - Also errors of refraction - The oblique muscles of accommodation - The recti concerned in the production of hypermetropia and astigmatism - No accommodation with one oblique cut, paralyzed, or absent - Paralysis of accommodation in experimental animals accomplished only by injection of atropine deep into the orbit, so as to reach the oblique muscles - Accommodation unaffected by removal of the lens - Fourth cranial nerve supplying superior oblique muscle a nerve of accommodation - Sources of error believed to have been eliminated in experiments.
- **Chapter V: The Truth about Accommodation as Demonstrated by a Study of Images Reflected from the Lens, Cornea, Iris and Sclera** Technique of Helmholtz defective - Image obtained by his method on the front of the lens not sufficiently distinct or stable to be measured - Failure of author to get reliable image with various sources of light - Success with 1,000-watt lamp, diaphragm and condenser - Image photographed - Images on cornea, iris, lens and sclera also photographed - Results confirmed earlier observations - Eyeball changes its shape during accommodation - Lens does not - Strain to see at near-point produces hypermetropia - Strain to see at distance myopia - Method of obtaining the corneal image.
- **Chapter VI: The Truth about Accommodation as Demonstrated by Clinical Observations** Results of experimental work confirmed by clinical observations - Atropine supposed to prevent accommodation - Conflict of facts with this theory - Normal accommodation observed in eyes under influence of atropine for long periods - Evidence of these cases against accepted theories overwhelming - Cases of accommodation in lensless eyes observed by author - Reality of the apparent act of accommodation demonstrated by the retinoscope - Evidence from the cure of presbyopia - Harmony of all clinical observations with views of accommodation and errors of refraction presented in this book.
- **Chapter VII: The Variability of the Refraction of the Eye** Refractive states supposed to be permanent - Retinoscope demonstrates the contrary - Normal sight never continuous - Refractive errors always changing - Conditions which produce errors of refraction - Variability of refractive states the cause of many accidents - Also of much statistical confusion.
- **Chapter XII: What Glasses Do to Us** The sins of Salvino degli Armati, reputed inventor of spectacles - How glasses harm the eyes - Sight never improved by them to normal - Always resented at first by the eye - Objects of vision distorted by them - Disagreeable sensations produced - Field of vision contracted - Difficulty of keeping the glass clean - Reflection of light

from lenses annoying and dangerous - Inconvenience of glasses to physically active persons - Effect on personal appearance - No muscular strain relieved by them - Apparent benefits often due to mental suggestion - Fortunate that many patients refuse to wear them - At best an unsatisfactory substitute for normal sight.

- **Chapter IX: Cause and Cure of Errors of Refraction** All abnormal action of external muscles of the eyeball accompanied by a strain to see - With relief of this strain all errors of refraction disappear - Myopia (or lessening of hypermetropia) associated with strain to see at the distance - Hypermetropia (or lessening of myopia) associated with strain to see at the near-point - Facts easily demonstrated by retinoscope - Effect of strain at the near-point accounts for apparent loss of accommodation in the lensless eye - Mental origin of eyestrain - Accounts for effect of civilization on the eye - Lower animals affected as man is - Remedy to get rid of mental strain - Temporary relaxation easy - Permanent relaxation may be difficult - Eyes not rested by sleep or tired by use - Rested only by resting the mind - Time required for a cure.
- **Chapter X: Strain** Foundation of the strain to see - Act of seeing passive - Same true of action of all sensory nerves - Their efficiency impaired when made the subject of effort - The mind the source of all such efforts brought to bear upon the eye - Mental strain of any kind produces eyestrain - This strain takes many forms - Results in production of many abnormal conditions - Circulation disturbed by strain - Normal circulation restored by mental control - Thus errors of refraction and other abnormal conditions are cured.
- **Chapter XI: Central Fixation** The center of sight - The eye normally sees one part of everything it looks at best - Central fixation lost in all abnormal conditions of the eye - Cause of mental strain - With central fixation the eye is perfectly at rest - Can be used indefinitely without fatigue - Open and quiet - No wrinkles or dark circles around it - Visual axes parallel - With eccentric fixation the contrary is the case - Eccentric fixation cured by any method that relieves strain - Limits of vision determined by central fixation - Organic diseases relieved or cured by it - No limit can be set to its possibilities - Relation to general efficiency and general health.
- **Chapter XII: Palming** Relaxation with the eyes shut - With light excluded by palms of the hands (palming) - Evidence of complete relaxation in palming - Of incomplete relaxation - Difficulties of palming - How dealt with - Futility of effort - All the sensory nerves relaxed by successful palming - Pain relieved in all parts of the body - Patients who succeed at once are quickly cured - A minority not helped and should try other methods.
- **Chapter XIII: Memory As an Aid to Vision** Memory a test of relaxation - Memory of black most suitable for the purpose - Application of this fact to treatment of functional eye troubles - Sensation not a reliable index of strain - Memory of black is - Enables the patient to avoid conditions that produce strain - Conditions favorable to memory - Retention of memory under unfavorable conditions - Quick cures by its aid - A great help to other mental processes - Tests of a perfect memory.
- **Chapter XIV: Imagination As an Aid to Vision** Retinal impressions interpreted by the mind -

Memory or imagination normally used as an aid to sight - In imperfect sight the mind adds imperfections to the imperfect retinal image - Only a small part of the phenomena of refractive errors accounted for by the inaccuracy of the focus - Difference between the photographic picture when the camera is out of focus and the visual impressions of the mind when the eye is out of focus - Patients helped by understanding of this fact - Dependence of imagination upon memory - Coincidence of both with sight - Perfect imagination dependent upon relaxation - Therefore imagination cures - Method of using it for this purpose - Remarkable cures effected by it.

- **Chapter XV: Shifting and Swinging** Apparent movement of objects regarded with normal vision - Due to unconscious shifting of the eye - Impossibility of fixing a point for an appreciable length of time - Lowering of vision by attempt to do so - Inconspicuousness of normal shifting - Its incredible rapidity - Staring an important factor in the production of imperfect sight - Tendency to stare corrected by conscious shifting and realization of apparent movement resulting from it - Conditions of success with shifting - The universal swing - Methods of shifting - Cures effected by this means.
- **Chapter XVI: The Illusions of Imperfect and of Normal Sight** Normal and abnormal illusions - Illusions of color - Of size - Of form - Of number - Of location - Of nonexistent objects - Of complementary colors - Of the color of the sun - Blind spots - Twinkling stars - Cause of illusions of imperfect sight - Voluntary production of illusions - Illusions of central fixation - Normal illusions of color - Illusions produced by shifting - The upright position of objects regarded an illusion.
- **Chapter XVII: Vision Under Adverse Conditions a Benefit to the Eye*** Erroneous ideas of ocular hygiene - Conditions supposedly injurious may be a benefit to the eye - No foundation for universal fear of the light - Of looking at a strong electric light - Not light but darkness a danger to the eye - Sudden contrasts of light may be beneficial - Advantages of the movies - Benefits of reading fine print - Reading in moving vehicles - In a recumbent posture - Vision under difficult conditions good mental training.
- **Chapter XVIII: Optimisms and Pessimisms** All objects not seen equally well when sight is imperfect - The eye has its optimisms and pessimisms - Some easily accounted for - Others unaccountable - Familiar objects optimisms - Unfamiliar objects pessimisms - Examples of unaccountable optimisms and pessimisms - Variability of optimisms and pessimisms - Test card usually a pessimism - Pessimisms which the patient is not conscious of seeing - Pessimisms associated with a strain to see - How pessimisms may become optimisms.
- **Chapter XIX: The Relief of Pain and Other Symptoms by the Aid of the Memory** No pain felt when the memory is perfect - All the senses improved - Efficiency of the mind increased - Operations performed without anaesthetics - Organic disorders relieved - Facts not fully explained, but attested by numerous proofs - Possible relationship of the principle involved to cures of Faith Curists and Christian Scientists.

- **Chapter XX: Presbyopia: Its Cause and Cure** Failure of near vision as age advances - Supposed normality of this phenomenon - Near-points expected at different ages - Many do not fit this schedule - Some never become presbyopic - Some retain normal vision for some objects while presbyopic for others - First and second of these classes of cases explained away or ignored - Third not heretofore observed - Presbyopia both preventable and curable - Due to a strain to see at the near-point - No necessary connection with age - Lens may flatten and lose refractive power with advancing years, but not necessarily - Temporary increase of presbyopia by strain at the nearpoint - Temporary relief by closing the eyes or palming - Permanent relief by permanent relief of strain - How the author cured himself - Other cures - Danger of putting on glasses at the presbyopic age - Prevention of presbyopia.
- **Chapter XXI: Squint and Amblyopia: Their Cause** Definition of squint - Theories as to its cause - Failure of these theories to fit the facts - Failure of operative treatment - State of the vision not an important factor - Amblyopia ex anopsia - Association with squint not invariable - Supposed incurability - Spontaneous recovery - Curious forms of double vision in squint - Invariable association of squint and amblyopia with strain - Invariable relief following relief of strain - Voluntary production of squint by strain.
- **Chapter XXII: Squint and Amblyopia: Their Cure** Squint and amblyopia purely functional troubles - Cured by any method that relieves strain - Relaxation sometimes gained by voluntary increase of squint, or production of other kinds - Remarkable cure effected in this way - Strain relieved when patient is able to look more nearly in the proper direction - Proper use of a squinting eye encouraged by covering the good eye - Children cured by use of atropine in one or both eyes - Examples of cases cured by eye education.
- **Chapter XXIII: Floating Specks: Their Cause and Cure** Floating specks a common phenomenon of imperfect sight - Their appearance and behavior - Theories as to their origin - A fruitful field for the patent-medicine business - Examples of the needless alarm they have caused - May be seen at times by any one - Simply an illusion caused by mental strain - This strain easily relieved - Illustrative cases.
- **Chapter XXIV: Home Treatment** Many persons can cure themselves of defective sight - Only necessary to follow a few simple directions - How to test the sight - Children who have not worn glasses cured by reading the Snellen test card every day - Adults of the same class also benefited in a short time - Cases of adults and children who have worn glasses more difficult - Glasses must be discarded - How to make a test card - Need of a teacher in difficult cases - Qualifications of such teachers - Duty of parents.
- **Chapter XXV: Correspondence Treatment** Correspondence treatment usually regarded as quackery - Impossible in the case of most diseases - Errors of refraction, not being diseases, admit of such treatment - Glasses successfully fitted by mail - Less room for failure in correspondence treatment of imperfect sight without glasses - Personal treatment more satisfactory, but not always available - Examples of cases cured by correspondence - Need for the co-operation of local

practitioners in such treatment.

- **Chapter XXVI: The Prevention of Myopia in Schools: Methods That Failed** A much debated question - Literature on the subject voluminous and unreliable - All that is certainly known - Studies of Cohn - Confirmation of his observations by other investigators in America and Europe - Increase of myopia during school life unanimously attributed to near work - Inadequacy of this theory - Failure of preventive measures based upon it - New difficulties - The appeal to heredity - To natural adaptation - Objections to these views - Why all preventive measures have failed.
- **Chapter XXVII: The Prevention and Cure of Myopia and Other Errors of Refraction in Schools: A Method That Succeeded** Production of eyestrain by unfamiliar objects - Relief by familiar objects - Facts furnish the means of preventing and curing errors of refraction in schools - By this means children often gain normal vision with incredible rapidity - Results in schools of Grand Forks, N. D.; New York, and other cities - Improvement in mentality of children as eyesight improved - Reformation of truants and incorrigibles - Hypermetropia and astigmatism prevented and cured - Method succeeded best when teachers did not wear glasses - Success would be greater still under a more rational educational system - Prevalence of defective sight in American children - Its results - Practically all cases preventable and curable - Inexpensiveness of method recommended - Imposes no additional burden on the teachers - Cannot possibly hurt the children - Directions for its use.
- **Chapter XXVIII: The Story of Emily** Cure of defective eyesight by cured patients - Cures of fellow students, parents and friends by school children - Remarkable record of Emily - An illustration of the benefits to be expected from the author's method of preventing and curing imperfect sight in school children.
- **Chapter XXIX: Mind and Vision** Poor sight one of the most fruitful causes of retardation in schools - More involved in it than inability to see - The result of an abnormal condition of the mind - This cannot be changed by glasses - Memory among faculties impaired when vision is impaired - Memory of primitive man may have been due to the same cause as his keen vision - A modern example of primitive memory combined with primitive keenness of vision - Correspondence between differences in the faculty of memory and differences in visual acuity - Memory and eyesight of children spoiled by the same causes - Both dependent upon interest - Illustrative cases - All the mental faculties improved when vision becomes normal - Examples of such improvement - Relief of symptoms of insanity by eye education - Facts indicate a close relation between the problems of vision and those of education.
- **Chapter XXX: Normal Sight and the Relief of Pain for Soldiers and Sailors** Growth of militarism in the United States - Demand for universal military training - Lack of suitable material for such training - Defective eyesight greatest impediment to the raising of an efficient army - None more easily removed - Plan for correcting defects of vision submitted to Surgeon General during the war - Not acted upon - Now presented to the public with some modifications - First requisite eye education in schools and colleges - Eye education in training camps and at the front

also needed, even for those whose sight is normal - How school system might be modified for military and naval use - Soldiers should not be allowed to wear glasses - Importance of eye training to aviators - Eye training for the relief of pain.

- [Chapter XXXI: Letters from Patients](#) Army officer cures himself - A teacher's experiences - Mental effects of central fixation - Relief after twentyfive years - Search for myopia cure rewarded - Facts versus theories - Cataract relieved by central fixation.
- [Chapter XXXII: Reason and Authority](#) Inaccessibility of average mind to reason - Facts discredited if contrary to authority - Patients discredit their own experience' under this influence - Cure of cataract ignored by medical profession - Expulsion of author from N. Y. Post Graduate Medical School for curing myopia - Man not a reasoning being - Consequences to the world.

Revised 1 May 2004

THE FUNDAMENTAL PRINCIPLE

Do you read imperfectly? Can you observe then that when you look at the first word, or the first letter, of a sentence you do not see best where you are looking; that you see other words, or other letters, just as well as or better than the one you are looking at? Do you observe also that the harder you try to see the worse you see?

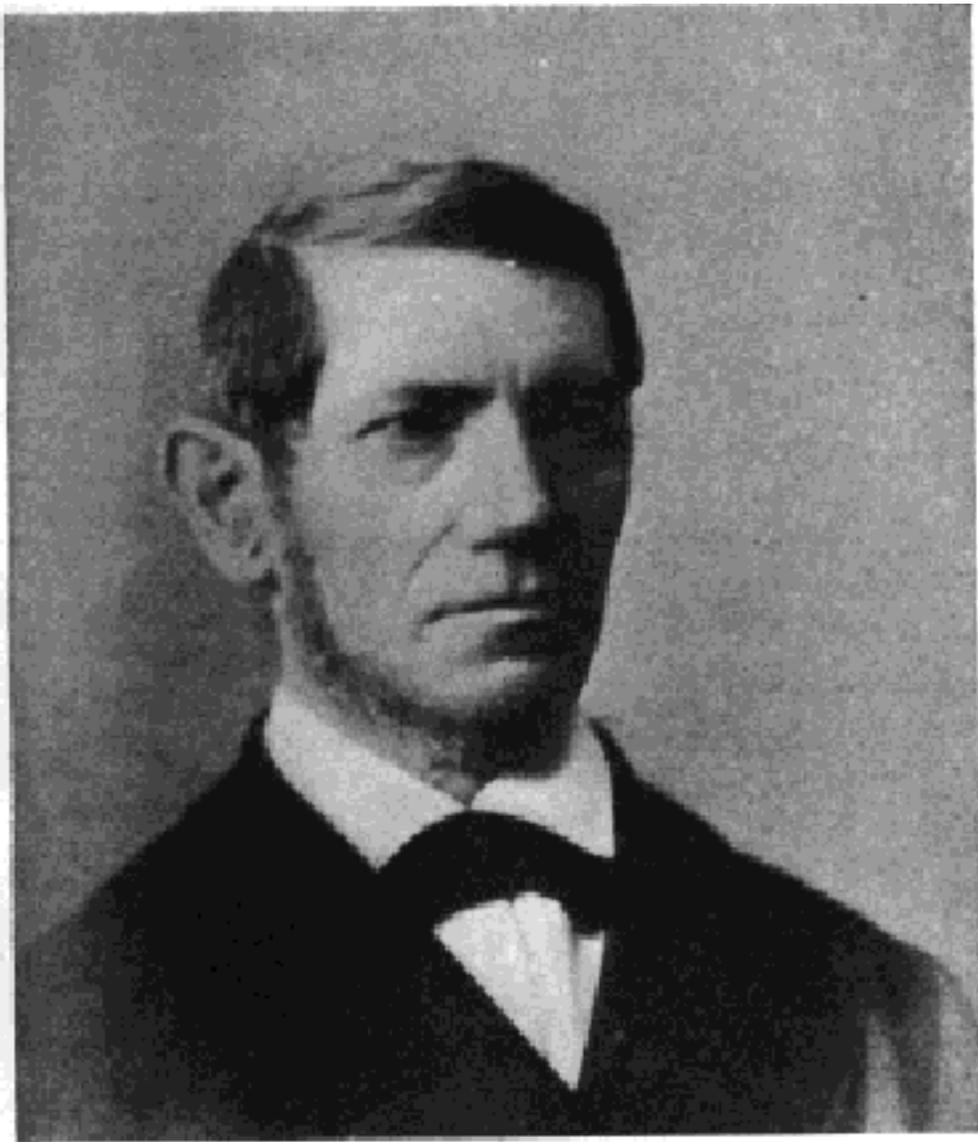

Now close your eyes and rest them, remembering some color, like black or white, that you can remember perfectly. Keep them closed until they feel rested, or until the feeling of strain has been completely relieved. Now open them and look at the first word or letter of a sentence for a fraction of a second. If you have been able to relax, partially or completely, you will have a flash of improved or clear vision, and the area seen best will be smaller.

After opening the eyes for this fraction of a second, close them again quickly, still remembering the color, and keep them closed until they again feel rested. Then again open them for a fraction of a second. Continue this alternate resting of the eyes and flashing of the letters for a time, and you may soon find that you can keep your eyes open longer than a fraction of a second without losing the improved vision.

If your trouble is with distant instead of near vision, use the same method with distant letters.

In this way you can demonstrate for yourself the fundamental principle of the cure of imperfect sight by treatment without glasses.

If you fail, ask someone with perfect sight to help you.

FERDINAND VON ARLT

(1812-1887)

Distinguished Austrian ophthalmologist, Professor of Diseases of the Eye at Vienna who believed for a time that accommodation was produced by an elongation of the visual axis, but finally, accepted the conclusions of Cramer and Helmholtz.

The Cure of Imperfect Sight

TO THE MEMORY

OF THE
PIONEERS OF OPHTHALMOLOGY
THIS BOOK IS GRATEFULLY DEDICATED

PREFACE

This book aims to be a collection of facts and not of theories, and insofar as it is, I do not fear successful contradiction. When explanations have been offered it has been done with considerable trepidation, because I have never been able to formulate a theory that would withstand the test of the facts either in my possession at the time, or accumulated later. The same is true of the theories of every other man, for a theory is only a guess, and you cannot guess or imagine the truth. No one has ever satisfactorily answered the question, "Why ?" as most scientific men are well aware, and I did not feel that I could do better than others who had tried and failed. One cannot even draw conclusions safely from facts, because a conclusion is very much like a theory, and may be disproved or modified by facts accumulated later. In the science of ophthalmology, theories, often stated as facts, have served to obscure the truth and throttle investigation for more than a hundred years. The explanations of the phenomena of sight put forward by Young, von Graefe, Helmholtz and Donders have caused us to ignore or explain away a multitude of facts which otherwise would have led to the discovery of the truth about errors of refraction and the consequent prevention of an incalculable amount of human misery.

In presenting my experimental work to the public, I desire to acknowledge my indebtedness to Mrs. E. C. Lierman, whose co-operation during four years of arduous labor and prolonged failure made it possible to carry

vii

viii Preface

the work to a successful issue. I would be glad, further, to acknowledge my debt to others who aided me with suggestions, or more direct assistance, but am unable to do so, as they have requested me not to mention their names in this connection.

As there has been a considerable demand for the book from the laity, an effort has been made to present the subject in such a way as to be intelligible to persons unfamiliar with ophthalmology.

CONTENTS

PAGE

Preface *vii*

CHAPTER I

Introductory 1

Prevalence of errors of refraction - Believed to be incurable and practically unpreventable - The eye regarded as a blunder of Nature - Facts which seem to justify this conclusion - Failure of all efforts to prevent the development of eye defects - Futility of prevailing methods of treatment - Conflict of facts with the theory of incurability of errors of refraction - These facts commonly explained away or ignored - The author unable to ignore them, or to accept current explanations - Finally forced to reject accepted theories.

CHAPTER II

Simultaneous Retinoscopy 17

Retinoscopy the source of much of the information presented in this book - What the retinoscope is - Its possibilities not realized - Commonly used only under artificial conditions - Used by the author under the conditions of life on human beings and the lower animals - Thus many new facts were discovered - Conflict of these facts with accepted theories - Resulting investigations.

CHAPTER III

Evidence For the Accepted Theory of Accommodation 23

Development of the theory - Behavior of the lens in accommodation as noted by Helmholtz - General acceptance of these observations as facts - Abandonment by Arlt of the true explanation of accommodation - Inability of Helmholtz to explain satisfactorily the supposed change of form in the lens - Question still unsettled - Apparent accommodation in lensless eyes - Curious and unscientific theories advanced to account for it - Voluntary production of astigmatism - Impossibility of reconciling it with the theory of an inextensible eyeball.

The Truth About Accommodation As Demonstrated By Experiments on the Eye Muscles of Fish, Cats, Dogs, Rabbits and Other Animals 38

Disputed function of the external muscles of the eyeball - Once regarded as possible factors in accommodation - This idea dismissed after supposed demonstration that accommodation depends upon the lens - Author's experiments demonstrate that accommodation depends wholly upon these muscles - Accommodation prevented and produced at will by their manipulation - Also errors of refraction - The oblique muscles of accommodation - The recti concerned in the production of hypermetropia and astigmatism - No accommodation with one oblique cut, paralyzed, or absent - Paralysis of accommodation in experimental animals accomplished only by injection of atropine deep into the orbit, so as to reach the oblique muscles - Accommodation unaffected by removal of the lens - Fourth cranial nerve supplying superior oblique muscle a nerve of accommodation - Sources of error believed to have been eliminated in experiments.

CHAPTER V

The Truth About Accommodation As Demonstrated By a Study of Images Reflected From the Cornea, Iris, Lens and Sclera 54

Technique of Helmholtz defective - Image obtained by his method on the front of the lens not sufficiently distinct or stable to be measured - Failure of author to get reliable image with various sources of light - Success with 1,000-watt lamp, diaphragm and condenser - Image photographed - Images on cornea, iris, lens and sclera also photographed - Results confirmed earlier observations - Eyeball changes its shape during accommodation - Lens does not - Strain to see at near-point produces hypermetropia - Strain to see at distance myopia - Method of obtaining the corneal image.

CHAPTER VI

The Truth About Accommodation As Demonstrated By Clinical Observations . 69

Results of experimental work confirmed by clinical observations - Atropine supposed to prevent accommodation - Conflict of facts with this theory - Normal accommodation observed in eyes under influence of atro-

pine for long periods - Evidence of these cases against accepted theories overwhelming - Cases of accommodation in lensless eyes observed by author - Reality of the apparent act of accommodation demonstrated by the retinoscope - Evidence from the cure of presbyopia - Harmony of all clinical observations with views of accommodation and errors of refraction presented in this book.

CHAPTER VII

The Variability of the Refraction of the Eye . . 75

Refractive states supposed to be permanent - Retinoscope demonstrates the contrary - Normal sight never continuous - Refractive errors always changing - Conditions which produce errors of refraction - Variability of refractive states the cause of many accidents - Also of much statistical confusion.

CHAPTER VIII

What Glasses Do to Us 81

The sins of Salvino degli Armati, reputed inventor of spectacles - How glasses harm the eyes - Sight never improved by them to normal - Always resented at first by the eye - Objects of vision distorted by them - Disagreeable sensations produced - Field of vision contracted - Difficulty of keeping the glass clean - Reflection of light from lenses annoying and dangerous - Inconvenience of glasses to physically active persons - Effect on personal appearance - No muscular strain relieved by them - Apparent benefits often due to mental suggestion - Fortunate that many patients refuse to wear them - At best an unsatisfactory substitute for normal sight.

CHAPTER IX

Cause and Cure of Errors of Refraction . . 89

All abnormal action of external muscles of the eyeball accompanied by a strain to see - With relief of this strain all errors of refraction disappear - Myopia (or lessening of hypermetropia) associated with strain to see at the distance - Hypermetropia (or lessening of myopia) associated with strain to see at the near-point - Facts easily demonstrated by retinoscope - Effect of strain at the near-point accounts for apparent loss of accommodation in the lensless eye - Mental origin of eyestrain - Accounts for effect of civilization on the eye - Lower animals affected as man is - Remedy to get rid of mental strain - Temporary relaxation easy - Permanent relaxation may be difficult - Eyes not rested by sleep or tired by use - Rested only by resting the mind - Time required for a cure.

CHAPTER X

Strain 106

Foundation of the strain to see - Act of seeing passive - Same true of action of all sensory nerves - Their efficiency impaired when made the subject of effort - The mind the source of all such efforts brought to bear upon the eye -

xii Contents

PAGE

Mental strain of any kind produces eyestrain - This strain takes many forms - Results in production of many abnormal conditions - Circulation disturbed by strain - Normal circulation restored by mental control - Thus errors of refraction and other abnormal conditions are cured.

CHAPTER XI

Central Fixation 114

The center of sight - The eye normally sees one part of everything it looks at best - Central fixation lost in all abnormal conditions of the eye - Cause of mental strain - With central fixation the eye is perfectly at rest - Can be used indefinitely without fatigue - Open and quiet - No wrinkles or dark circles around it - Visual axes parallel - With eccentric fixation the contrary is the case - Eccentric fixation cured by any method that relieves strain - Limits of vision determined by central fixation - Organic diseases relieved or cured by it - No limit can be set to its possibilities - Relation to general efficiency and general health.

CHAPTER XII

Palming 123

Relaxation with the eyes shut - With light excluded by palms of the hands (palming) - Evidence of complete relaxation in palming - Of incomplete relaxation - Difficulties of palming - How dealt with - Futility of effort - All the sensory nerves relaxed by successful palming - Pain relieved in all parts of the body - Patients who succeed at once are quickly cured- A minority not helped and should try other methods.

Contents xiii

Memory As an Aid to Vision 136

Memory a test of relaxation - Memory of black most suitable for the purpose - Application of this fact to treatment of functional eye troubles - Sensation not a reliable index of strain - Memory of black is - Enables the patient to avoid conditions that produce strain - Conditions favorable to memory - Retention of memory under unfavorable conditions - Quick cures by its aid - A great help to other mental processes - Tests of a perfect memory.

CHAPTER XIV

Imagination As an Aid to Vision 148

Retinal impressions interpreted by the mind - Memory or imagination normally used as an aid to sight - In imperfect sight the mind adds imperfections to the imperfect retinal image - Only a small part of the phenomena of refractive errors accounted for by the inaccuracy of the focus - Difference between the photographic picture when the camera is out of focus and the visual impressions of the mind when the eye is out of focus - Patients helped by understanding of this fact - Dependence of imagination upon memory - Coincidence of both with sight - Perfect imagination dependent upon relaxation - Therefore imagination cures - Method of using it for this purpose - Remarkable cures effected by it.

CHAPTER XV

Shifting and Swinging 159

Apparent movement of objects regarded with normal vision - Due to unconscious shifting of the eye - Impossibility of fixing a point for an appreciable length of time - Lowering of vision by attempt to do so - Inconspicuousness of normal shifting - Its incredible rapidity - Staring an important factor in the production of imperfect sight - Tendency to stare corrected by conscious shifting and realization of apparent movement resulting from it - Conditions of success with shifting - The universal swing - Methods of shifting - Cures effected by this means.

CHAPTER XVI

The Illusions of Imperfect and of Normal Sight . . 172

Normal and abnormal illusions - Illusions of color - Of size - Of form - Of number - Of location - Of nonexistent objects - Of complementary colors - Of the

xiv Contents

color of the sun - Blind spots - Twinkling stars - Cause of illusions of imperfect sight - Voluntary production of illusions - Illusions of central fixation - Normal illusions of color - Illusions produced by shifting - The upright position of objects regarded an illusion.

CHAPTER XVII

Vision Under Adverse Conditions a Benefit to the Eye . . . 183

Erroneous ideas of ocular hygiene - Conditions supposedly injurious may be a benefit to the eye - No foundation for universal fear of the light - Temporary discomfort but no permanent injury from it - Benefits of sun-gazing - Of looking at a strong electric light - Not light but darkness a danger to the eye - Sudden contrasts of light may be beneficial - Advantages of the movies - Benefits of reading fine print - Reading in moving vehicles - In a recumbent posture - Vision under difficult conditions good mental training.

CHAPTER XVIII

Optimums and Pessimums 198

All objects not seen equally well when sight is imperfect - The eye has its optimums and pessimums - Some easily accounted for - Others unaccountable - Familiar objects optimums - Unfamiliar objects pessimums - Examples of unaccountable optimums and pessimums - Variability of optimums and pessimums - Test card usually a pessimum - Pessimums which the patient is not conscious of seeing - Pessimums associated with a strain to see - How pessimums may become optimums.

CHAPTER XIX

The Relief of Pain and Other Symptoms by the Aid of the Memory

.202

No pain felt when the memory is perfect - All the senses improved - Efficiency of the mind increased - Operations performed without anaesthetics - Organic disorders relieved - Facts not fully explained, but attested by numerous proofs - Possible relationship of the principle involved to cures of Faith Curists and Christian Scientists.

Presbyopia: Its Cause and Cure . . . 210

Failure of near vision as age advances - Supposed normality of this phenomenon - Near-points expected at different ages - Many do not fit this schedule - Some never become presbyopic - Some retain normal vision for some objects while presbyopic for others - First and second of these classes of cases explained away or ignored - Third not heretofore observed - Presbyopia both preventable and curable - Due to a strain to see at the near-point - No necessary connection with age - Lens may flatten and lose refractive power with advancing years, but not necessarily - Temporary increase of presbyopia by strain at the nearpoint - Temporary relief by closing the eyes or palming - Permanent relief by permanent relief of strain - How the author cured himself - Other cures - Danger of putting on glasses at the presbyopic age - Prevention of presbyopia.

CHAPTER XXI

Squint and Amblyopia: Their Cause .221

Definition of squint - Theories as to its cause - Failure of these theories to fit the facts - Failure of operative treatment - State of the vision not an important factor - Amblyopia ex anopsia - Association with squint not invariable - Supposed incurability - Spontaneous recovery - Curious forms of double vision in squint - Invariable association of squint and amblyopia with strain - Invariable relief following relief of strain - Voluntary production of squint by strain.

CHAPTER XXII

Squint and Amblyopia: Their Cure. . 227

Squint and amblyopia purely functional troubles - Cured by any method that relieves strain - Relaxation sometimes gained by voluntary increase of squint, or production of other kinds - Remarkable cure effected in this way - Strain relieved when patient is able to look more nearly in the proper direction - Proper use of a squinting eye encouraged by covering the good eye - Children cured by use of atropine in one or both eyes - Examples of cases cured by eye education.

xvi Contents

Floating Specks: Their Cause and Cure . 236

Floating specks a common phenomenon of imperfect sight - Their appearance and behavior -

Theories as to their origin - A fruitful field for the patent-medicine business - Examples of the needless alarm they have caused - May be seen at times by any one - Simply an illusion caused. by mental strain - This strain easily relieved - Illustrative cases.

CHAPTER XXIV

Home Treatment . . 242

Many persons can cure themselves of defective sight - Only necessary to follow a few simple directions - How to test the sight - Children who have not worn glasses cured by reading the Snellen test card every day - Adults of the same class also benefited in a short time - Cases of adults and children who have worn glasses more difficult - Glasses must be discarded - How to make a test card - Need of a teacher in difficult cases - Qualifications of such teachers - Duty of parents.

CHAPTER XXV

Correspondence Treatment 246

Correspondence treatment usually regarded as quackery - Impossible in the case of most diseases - Errors of refraction, not being diseases, admit of such treatment - Glasses successfully fitted by mail - Less room for failure in correspondence treatment of imperfect sight without glasses - Personal treatment more satisfactory, but not always available - Examples of cases cured by correspondence - Need for the co-operation of local practitioners in such treatment.

CHAPTER XXVI

The Prevention of Myopia in Schools: Methods That Failed . . 251

A much debated question - Literature on the subject voluminous and unreliable - All that is certainly known - Studies of Cohn - Confirmation of his observations by other investigators in America and Europe - Increase of myopia during school life unanimously attributed to near work - Inadequacy of this theory - Failure of preventive measures based upon it - New difficulties - The appeal to heredity - To natural adaptation - Objections to these views - Why all preventive measures have failed.

Contents xvii

CHAPTER XXVII PAGE

The Prevention and Cure of Myopia and Other Errors of Refraction in Schools: A Method That

Succeeded 259

Production of eyestrain by unfamiliar objects - Relief by familiar objects - Facts furnish the means of preventing and curing errors of refraction in schools - By this means children often gain normal vision with incredible rapidity - Results in schools of Grand Forks, N. D.; New York, and other cities - Improvement in mentality of children as eyesight improved - Reformation of truants and incorrigibles - Hypermetropia and astigmatism prevented and cured - Method succeeded best when teachers did not wear glasses - Success would be greater still under a more rational educational system - Prevalence of defective sight in American children - Its results - Practically all cases preventable and curable - Inexpensiveness of method recommended - Imposes no additional burden on the teachers - Cannot possibly hurt the children - Directions for its use.

CHAPTER XXVIII

The Story of Emily 270

Cure of defective eyesight by cured patients - Cures of fellow students, parents and friends by school children - Remarkable record of Emily - An illustration of the benefits to be expected from the author's method of preventing and curing imperfect sight in school children.

CHAPTER XXIX

Mind and Vision 274

Poor sight one of the most fruitful causes of retardation in schools - More involved in it than inability to see - The result of an abnormal condition of the mind - This cannot be changed by glasses - Memory among faculties impaired when vision is impaired - Memory of primitive man may have been due to the same cause as his keen vision - A modern example of primitive memory combined with primitive keenness of vision - Correspondence between differences in the faculty of memory and differences in visual acuity - Memory and eyesight of children spoiled by the same causes - Both dependent upon interest - Illustrative cases - All the mental faculties improved when vision becomes normal - Examples of such improvement - Relief of symptoms of insanity by eye education - Facts indicate a close relation between the problems of vision and those of education.

xviii *Contents*

CHAPTER XXX PAGE

Normal Sight and the Relief of Pain for Soldiers and Sailors . 284

Growth of militarism in the United States - Demand for universal military training - Lack of suitable material for such training - Defective eyesight greatest impediment to the raising of an

efficient army - None more easily removed - Plan for correcting defects of vision submitted to Surgeon General during the war - Not acted upon - Now presented to the public with some modifications - First requisite eye education in schools and colleges - Eye education in training camps and at the front also needed, even for those whose sight is normal - How school system might be modified for military and naval use - Soldiers should not be allowed to wear glasses - Importance of eye training to aviators - Eye training for the relief of pain.

CHAPTER XXXI

Letters from Patients 290

Army officer cures himself - A teacher's experiences - Mental effects of central fixation - Relief after twentyfive years - Search for myopia cure rewarded - Facts versus theories - Cataract relieved by central fixation.

CHAPTER XXXII

Reason and Authority 304

Inaccessibility of average mind to reason - Facts discredited if contrary to authority - Patients discredit their own experience' under this influence - Cure of cataract ignored by medical profession - Expulsion of author from N. Y. Post Graduate Medical School for curing myopia - Man not a reasoning being - Consequences to the world.

THE CURE OF IMPERFECT SIGHT BY TREATMENT WITHOUT GLASSES

CHAPTER I

INTRODUCTORY

MOST writers on ophthalmology appear to believe that the last word about problems of refraction has been spoken, and from their viewpoint the last word is a very depressing one. Practically everyone in these days suffers from some form of refractive error. Yet we are told that for these ills, which are not only so inconvenient, but often so distressing and dangerous, there is not only no cure, and no palliatives save those optic crutches known as eyeglasses, but, under modern conditions of life, practically no prevention.

It is a well known fact that the human body is not a perfect mechanism. Nature, in the evolution of the human tenement, has been guilty of some maladjustments. She has left, for instance, some troublesome bits of scaffolding, like the vermiform appendix, behind. But nowhere is she supposed to have blundered so badly as in the construction of the eye. With one accord ophthalmologists tell us that the visual organ of man was never intended for the uses to which it is now put. Eons before there were any schools or printing presses, electric lights or moving pictures, its evolution was complete. In those days it served the needs of the human animal perfectly. Man was a hunter, a herdsman, a farmer, a fighter. He needed, we are told, mainly distant vision;

1

2 Introductory

and since the eye at rest is adjusted for distant vision, sight is supposed to have been ordinarily as passive as the perception of sound, requiring no muscular action whatever. Near vision, it is assumed, was the exception,

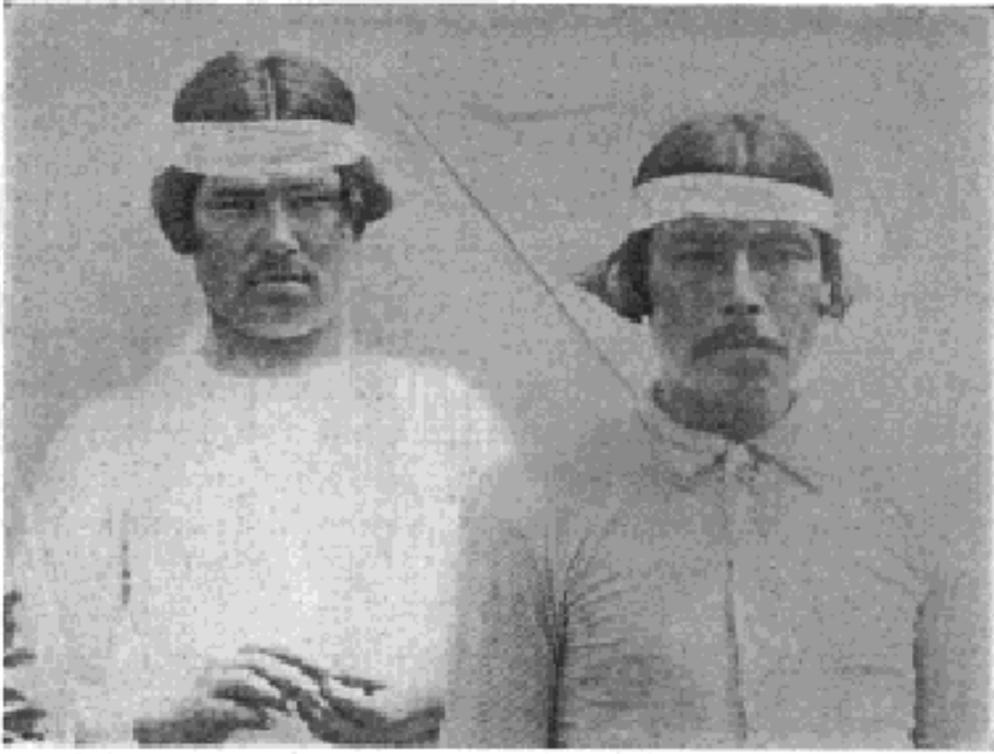

Fig. 1. Patagonians

The sight of this primitive pair and of the following groups of primitive people was tested at the World's Fair in St. Louis and found to be normal. The unaccustomed experience of having their pictures taken, however, has evidently so disturbed them that they were all, probably, myopic when they faced the camera. (see Chapter IX.)

necessitating a muscular adjustment of such short duration that it was accomplished without placing any appreciable burden upon the mechanism of accommodation. The fact that primitive woman was a seamstress, an embroiderer, a weaver, an artist in all sorts of fine and beautiful work, appears to have been generally forgotten. Yet

New Demands Upon the Eye 3

women living under primitive conditions have just as good eyesight as the men.

When man learned how to communicate his thoughts to others by means of written and printed forms, there came some undeniably new demands upon the eye, af-

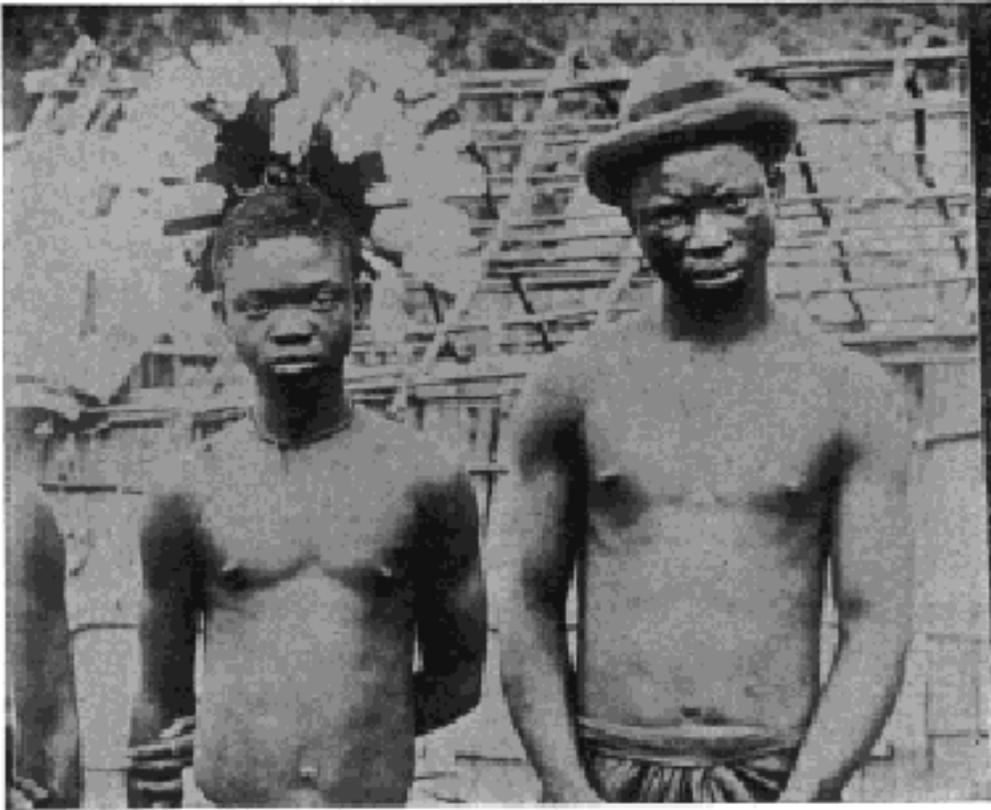

Fig. 2. African Pigmies

They had normal vision when tested, but their expressions show that they could not have had it when photographed.

fecting at first only a few people, but gradually including more and more, until now, in the more advanced countries, the great mass of the population is subjected to their influence. A few hundred years ago even princes were not taught to read and write. Now we compel everyone to go to school, whether he wishes to or not,

4 Introductory

even the babies being sent to kindergarten. A generation or so ago books were scarce and expensive. Today, by means of libraries of all sorts, stationary and traveling, they have been brought within the reach of practically everyone. The modern newspaper, with its endless columns of badly printed reading matter, was made possible only by the discovery of the art of manufacturing paper from wood, which is a-thing of yesterday. The tallow candle has been but lately displaced by the various forms of artificial lighting, which tempt most of us to prolong our vocations and avocations into hours when primitive man was forced to rest, and within the last couple of decades has come the moving picture to complete the supposedly destructive process.

Was it reasonable to expect that Nature should have provided for all these developments, and produced an

organ that could respond to the new demands? It is the accepted belief of ophthalmology to-day that she could not and did not,¹ and that, while the processes of civilization depend upon the sense of sight more than upon any other, the visual organ is but imperfectly fitted for its tasks.

There are a great number of facts which seem to justify this conclusion. While primitive man appears to have suffered little from defects of vision, it is safe to say that

¹ The unnatural strain of accommodating the eyes to close work (for which they were not intended) leads to myopia in a large proportion of growing children - Rosenau Preventive Medicine and Hygiene, third edition, 1917, p. 1093.

The compulsion of fate as well as an error of evolution has brought it about that the unaided eye must persistently struggle against the astonishing difficulties and errors inevitable in its structure function and circumstance - Gould The Cause, Nature and Consequences of Eyestrain, Pop Sci Monthly,

Dec., 1905.

With the invention of writing and then with the invention of the printing-press a new element was introduced, and one evidently not provided for by the process of evolution The human eye which had been evolved for distant vision is being forced to perform a new part, one for which it had not been evolved, and for which it is poorly adapted The difficulty is being daily augmented - Scott The Sacrifice of the Eyes of School Children, Pop

Sci Monthly, Oct., 1907

Military Visual Standards 5

of persons over twenty-one living under civilized conditions nine out of every ten have imperfect sight, and as the age increases the proportion increases, until at forty it is almost impossible to find a person free from visual defects. Voluminous statistics are available to prove these assertions, but the visual standards of the modern army ¹ are all the evidence that is required.

In Germany, Austria, France and Italy the- vision with glasses determines acceptance or rejection for military service, and in all these countries more than six diopters ² of myopia are allowed, although a person so handicapped cannot, without glasses, see anything clearly at more than six inches from his eyes. In the German Army a recruit for general service is required - or was required under the former government - to have a corrected vision of 6/12 in one eye. That is, he must be able to read with this eye at six metres the line normally read at twelve metres. In other words, he is considered fit for military service if the vision of one eye can be brought up to one-half normal with glasses. The vision in the other eye may be minimal, end in the Landsturm one eye may be blind. Incongruous as the eyeglass seems upon the soldier, military authorities upon the European continent have come to the conclusion that a man with 6/12 vision wearing glasses is more serviceable than a man with 6/24 vision (one-quarter normal)

without them.

In Great Britain it was formerly uncorrected vision that determined acceptance or rejection for military service. This was probably due to the fact that previous to the recent war the British Army was used chiefly for

1 Ford Details of Military Medical Administration published with the approval of the Surgeon General, U.S. Army, second revised edition, 1918, pp. 498-499.

2 A diopter is the focussing power necessary to bring parallel rays to a focus at one metre.

6 Introductory

foreign service, at such distances from its base that there might have been difficulty in providing glasses. The standard at the beginning of the war was 6/24 (uncorrected) for the better eye and 6/60 (uncorrected) for the

Fig. 3. Moros from the Philippines

With sight ordinarily normal all were probably myopic when photographed except the one at the upper left whose eyes are shut.

poorer, which was required to be the left. Later, owing to the difficulty of securing enough men with even this moderate degree of visual acuity, recruits were accepted whose vision in the right eye could be brought up to 6/12 by correction, provided the vision of one eye was 6/24 without correction.¹

¹ Tr. Ophth. Soc. U. Kingdom, vol. xxxviii, 1918, pp. 130-131.

Lowering of American Standards 7

Up to 1908 the United States required normal vision in recruits for its military service. In that year Bannister and Shaw made some experiments from which they concluded that a perfectly sharp image of the target was not necessary for good shooting, and that, therefore, a visual acuity of 20/40 (the equivalent in feet of 6/12 in metres), or even 20/70, in the aiming eye only, was sufficient to make an efficient soldier. This conclusion was not accepted without protest, but normal vision had become so rare that it probably seemed to those in authority that there was no use insisting upon it; and the visual standard for admission to the Army was accordingly lowered to 20/40 for the better eye and 20/100 for the poorer, while it was further provided that a recruit might be accepted when unable with the better eye to read all the letters on the 20/40 line, provided he could read some of the letters on the 20/30 line.¹

In the first enrollment of troops for the European war it is a matter of common knowledge that these very low standards were found to be too high and were interpreted with great liberality. Later they were lowered so that men might be "unconditionally accepted for general military service" with a vision of 20/100 in each eye without glasses, provided that the sight of one eye could be brought up to 20/40 with glasses, while for limited service 20/200 in each eye was sufficient, provided the vision of one eye might be brought up to 20/40 with glasses.² Yet 21.68 per cent of all rejections in the first draft, 13 per cent more than for any other single cause, were for

8 Introductory

eye defects,¹ while under the revised standards these defects still constituted one of three leading causes of rejection. They were responsible for 10.65 per cent of the rejections, while defects of the bones and joints and of the heart and bloodvessels ran, respectively, about two and two and a half per cent higher.²

For more than a hundred years the medical profession has been seeking for some method of checking the ravages of civilization upon the human eye. The Germans, to whom the matter was one of vital military

importance, have spent millions of dollars in carrying out the suggestions of experts, but without avail; and it is now admitted by most students of the subject that the methods which were once confidently advocated as reliable safeguards for the eyesight of our children - have accomplished little or nothing. Some take a more cheerful view of the matter, but their conclusions are hardly borne out by the army standards just quoted.

For the prevailing method of treatment, by means of compensating lenses, very little was ever claimed except that these contrivances neutralized the effects of the various conditions for which they were prescribed, as a crutch enables a lame man to walk. It has also been believed that they sometimes checked the progress of these conditions; but every ophthalmologist now knows that their usefulness for this purpose, if any, is very limited. In the case of myopia ~~~~ (shortsight), Dr. Sidler-Huguenin of Zurich, in a striking paper recently pub

3 From the Greek *myein*, to close, and *ops*, the eye, literally a condition in which the subject closes the eye, or blinks.

Present Methods of Treatment Futile 9

lished,¹ expresses the opinion that glasses and all methods now at our command are "of but little avail" in preventing either the progress of the error of refraction, or the development of the very serious complications with which it is often associated.

These conclusions are based on the study of thousands of cases in Dr. Huguenin's private practice and in the clinic of the University of Zurich, and regarding one group of patients, persons connected with the local educational institutions, he states that the failure took place in spite of the fact that they followed his instructions for years "with the greatest energy and pertinacity," sometimes even changing their professions.

I have been studying the refraction of the human eye for more than thirty years, and my observations fully confirm the foregoing conclusions as to the uselessness of all the methods heretofore employed for the prevention and treatment of errors of refraction. I was very early led to suspect, however, that the problem was by no means an unsolvable one

Every ophthalmologist of any experience knows that the theory of the incurability of errors of refraction does not fit the observed facts. Not infrequently such cases recover spontaneously, or change from one form to another. It has long been the custom either to ignore these troublesome facts, or to explain them

away, and fortunately for those who consider it necessary to bolster up the old theories at all costs, the role attributed to the lens in accommodation offers, in the majority of cases, a plausible method of explanation. According to this

¹ Archiv f Augenh, vol. lxxix, 1915, translated in Arch. Ophth., vol. xlv, No. 6, Nov., 1916.

10 Introductory

theory, which most of us learned at school, the eye changes its focus for vision at different distances by altering the curvature of the lens; and in seeking for an explanation for the inconstancy of the theoretically constant error of refraction the theorists hit upon the very ingenious idea of attributing to the lens a capacity for changing its curvature, not only for the purpose of normal accommodation, but to cover up or to produce accommodative errors. In hypermetropia¹ - commonly but improperly called farsight, although the patient with such a defect can see clearly neither at the distance nor the nearpoint - the eyeball is too short from the front backward, and all rays of light, both the convergent ones coming from near objects, and the parallel ones coming from distant objects, are focussed behind the retina, instead of upon it. In myopia it is too long, and while the divergent rays from near objects come to a point upon the retina, the parallel ones from distant objects do not reach it. Both these conditions are supposed to be permanent, the one congenital, the other acquired. When, therefore, persons who at one time appear to have hypermetropia, or myopia, appear at other times not to have them, or to have them in lesser degrees, it is not permissible to suppose that there has been a change in the shape of the eyeball. Therefore, in the case of the disappearance or lessening of hypermetropia, we are asked to believe that the eye, in the act of vision, both at the near-point and at the distance, increases the curvature of the lens sufficiently to compensate, in whole or in part, for the flatness of the eyeball. In myopia, on the

¹ From the Greek *hyper*, over, *metrons*, measure, and *ops*, the eye.

An Ingenious Theory 11

contrary, we are told that the eye actually goes out of its way to produce the condition, or to make an existing condition worse. In other words, the so-called "ciliary

Myopic Eyeballs

H, hypermetropia; E, emmetropia; M, myopia; Ax, optic axis. Note that in hypermetropia and myopia the rays, instead of coming to a focus, form a round spot upon the retina.

muscle," believed to control the shape of the lens, is credited with a capacity for getting into a more or less continuous state of contraction, thus keeping the lens continuously in a state of convexity which, according

12 Introductory

to the theory, it ought to assume only for vision at the nearpoint. These curious performances may seem unnatural to the lay mind; but ophthalmologists believe the tendency to indulge in them to be so ingrained in the constitution of the organ of vision that, in the fitting of glasses, it is customary to instill atropine - the "drops" with which everyone who has ever visited an oculist is familiar - into the eye, for the purpose of paralyzing the ciliary muscle and thus, by preventing any change of curvature in the lens, bringing out "latent hypermetropia" and getting rid of "apparent myopia."

The interference of the lens, however, is believed to account for only moderate degrees of variation in

errors of refraction, and that only during the earlier years of life. For the higher ones, or those that occur after fortyfive years of age, when the lens is supposed to have lost its elasticity to a greater or less degree, no plausible explanation has ever been devised. The disappearance of astigmatism,' or changes in its character, present an even more baffling problem. Due in most cases to an unsymmetrical change in the curvature of the cornea, and resulting in failure to bring the light rays to a focus at any point, the eye is supposed to possess only a limited power of overcoming this condition; and yet astigmatism comes and goes with as much facility as do other errors of refraction. It is well known, too, that it can be produced voluntarily. Some persons can produce as much as three diopters. I myself can produce one and a half.

Examining 30,000 pairs of eyes a year at the New York Eye and Ear Infirmary and other institutions, I observed

1 From the Greek *a*, without, and *stigma*, a point

Orthodox Explanations Fail 13

many cases in which errors of refraction either recovered spontaneously, or changed their form, and I was unable either to ignore them, or to satisfy myself with

The eye: C, cornea where the rays of light undergo a first refraction; D, iris (the diaphragm of the camera); L, lens, where the light rays are again refracted; R, retina of the normal eye; AB, object of vision; ab, image in the normal or emmetropic eye- at b', image in the hypermetropic eye; a" b", image in the myopic eye. Note that in a' b' and a" b" the rays are spread out upon the retina instead of being brought to a focus as in ab, the result being the formation of a blurred image.

14 Introductory

the orthodox explanations, even where such explanations were available. It seemed to me that if a statement is a truth it must always be a truth. There can be no exceptions. If errors of refraction are incurable, they should not recover, or change their form, spontaneously.

In the course of time I discovered that myopia and hypermetropia, like astigmatism, could be produced at will; that myopia was not, as we have so long believed, associated with the use of the eyes at the near-point, but with a strain to see distant objects, strain at the near-point being associated with hypermetropia; that no error of refraction was ever a constant condition; and that the lower degrees of refractive error were curable, while higher degrees could be improved.

In seeking for light upon these problems I examined tens of thousands of eyes, and the more facts I accumulated the more difficult it became to reconcile them with the accepted views. Finally, about half a dozen years ago, I undertook a series of observations upon the eyes of human beings and the lower animals the results of which convinced both myself and others that the lens is not a factor in accommodation, and that the adjustment necessary for vision at different distances is affected in the eye, precisely as it is in the camera, by a change in the length of the organ, this alteration being brought about by the action of the muscles on the out

side of the globe. Equally convincing was the demonstration that errors of refraction, including presbyopia, are due, not to an organic change in the shape of the eyeball, or in the constitution of the lens, but to a functional and therefore curable derangement in the action of the extrinsic muscles.

The Compulsion of Facts 15

In making these statements I am well aware that I am controverting the practically undisputed teaching of ophthalmological science for the better part of a century;

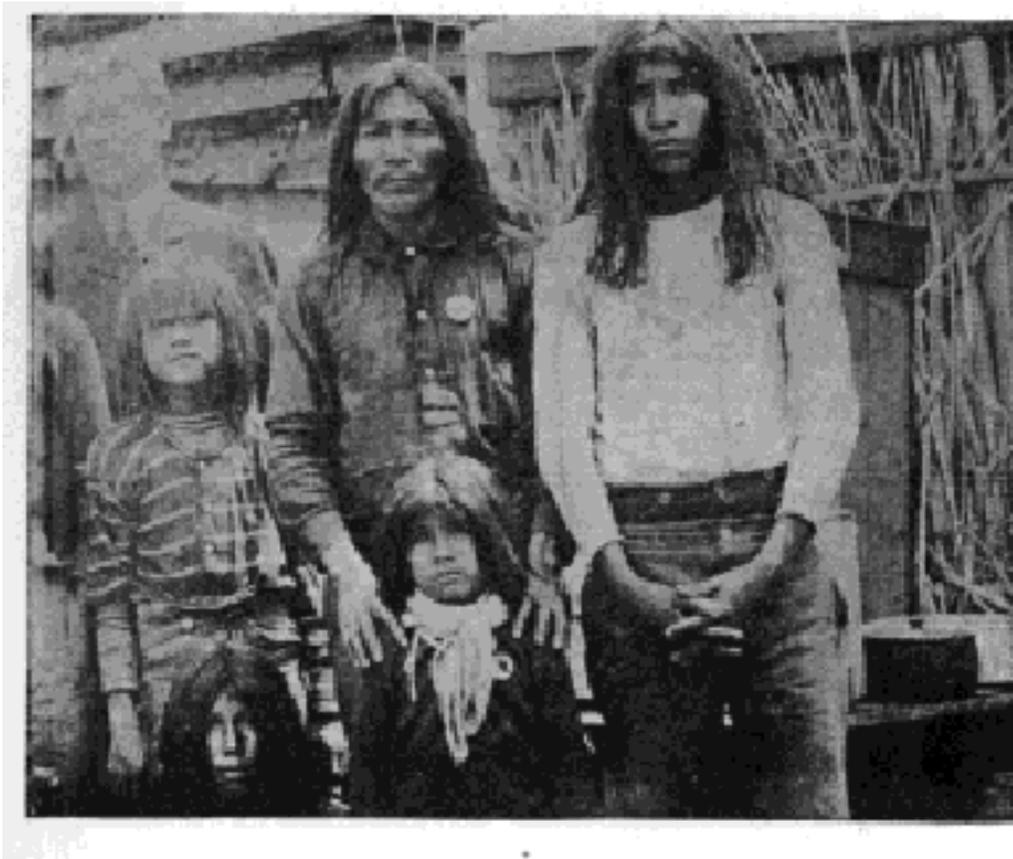

Fig. 6. Mexican Indians

With normal sight when tested all the members of this primitive group are now either squinting or staring.

but I have been driven to the conclusions which they embody by the facts, and that so slowly that I am now surprised at my own blindness. At the time I was improving high degrees of myopia; but I wanted to be conservative, and I differentiated between functional myopia,

16 Introductory

which I was able to cure, or improve, and organic myopia, which, in deference to the orthodox tradition, I accepted as incurable.

CHAPTER II

SIMULTANEOUS RETINOSCOPY

MUCH of my information about the eyes has been obtained by means of simultaneous retinoscopy.

The retinoscope is an instrument used to measure the refraction of the eye. It throws a beam of light into the pupil by reflection from a mirror,; the light being either outside the instrument - above and behind the subject - or arranged within it by means of an electric battery. On looking through the sight-hole one sees a larger or smaller part of the pupil filled with light, which in normal human eyes is a reddish yellow, because this is the color of the retina, but which is green in a cat's eye, and might be white if the retina were diseased. Unless the eye is exactly focussed at the point from which it is being observed, one sees also a dark shadow at the edge of the pupil, and it is the behavior of this shadow when the mirror is moved in various directions which reveals the refractive condition of the eye. If the instrument is used at a distance of six feet or more, and the shadow moves in a direction opposite to the movement of the mirror, the eye is myopic. If it moves in the same direction as the mirror, the eye is either hypermetropic or normal; but in the case of hypermetropia the movement is more pronounced than in that of normality, and an expert can usually tell the difference between the two states merely by the nature of the move-

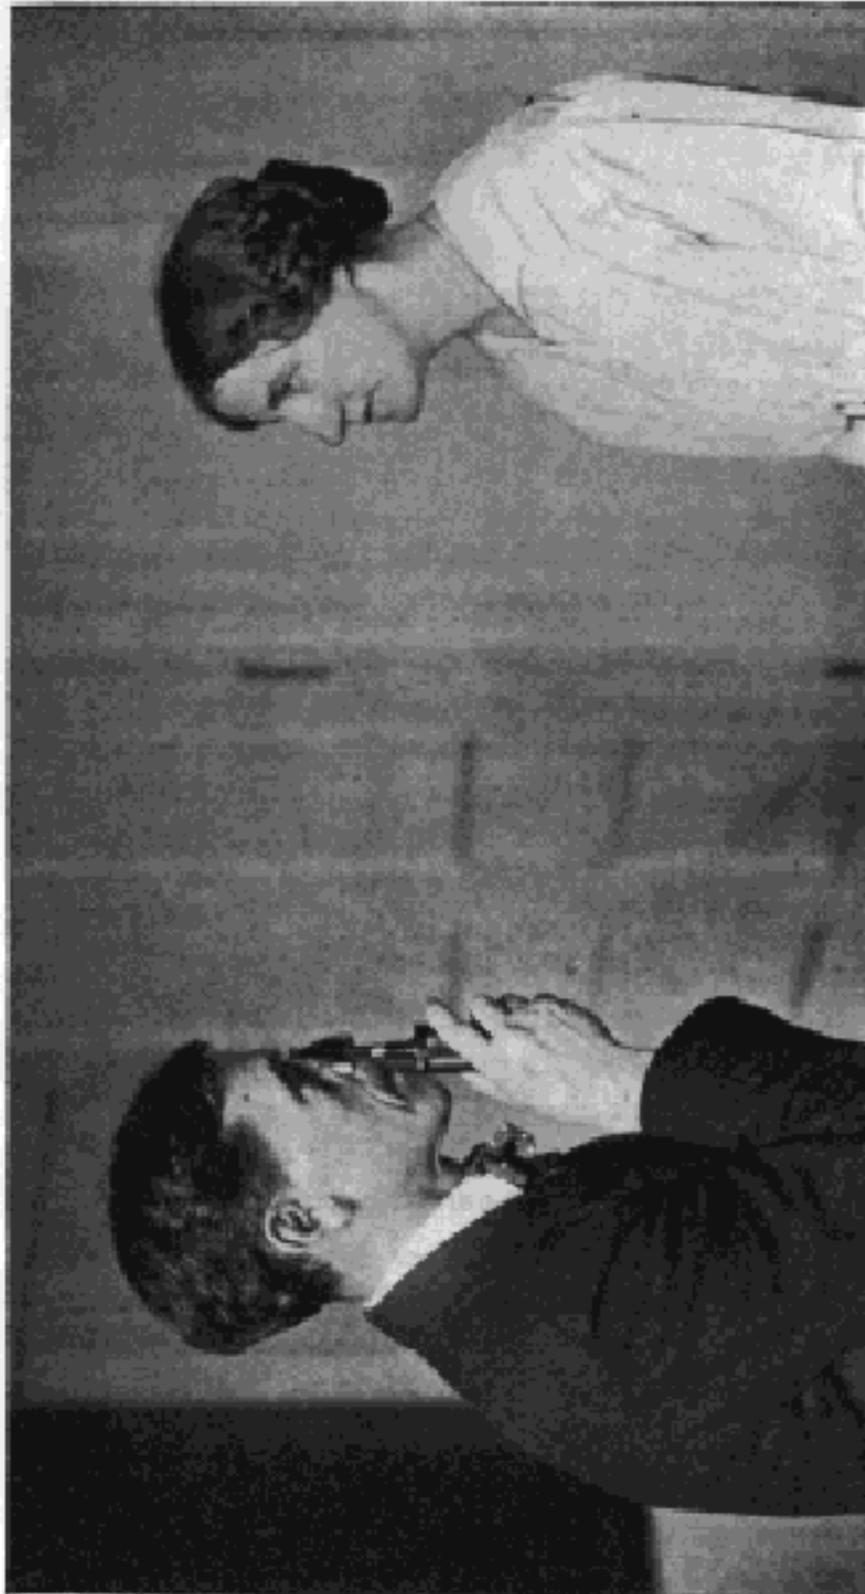

Fig. 8. The Usual Method of Using the Retinoscope

The observer is so near the subject that the latter is made nervous, and this changes the refraction.

Possibilities of Retinoscopy 19

ment. In astigmatism the movement is different in different meridians. To determine the degree of the error, or to distinguish accurately between hypermetropia and normality, or between the different kinds of astigmatism, it is usually necessary to place a glass before the eye of the subject. If the mirror is concave instead of plane, the movements described will be reversed; but the plane mirror is the one most commonly used.

This exceedingly useful instrument has possibilities which have not been generally realized by the medical profession. Most ophthalmologists depend upon the Snellen' test card, supplemented by trial lenses, to determine whether the vision is normal or not, and to determine the degree of any abnormality that may exist. This is a slow, awkward and unreliable method of testing the vision, and absolutely unavailable for the study of the refraction of the lower animals, of infants, and of adult human beings under the conditions of life.

The test card and trial lenses can be used only under certain favorable conditions, but the retinoscope can be used anywhere. It is a little easier to use it in a dim light than in a bright one, but it may be used in any light, even with the strong light of the sun shining directly into the eye. It may also be used under many other unfavorable conditions.

It takes a considerable time, varying from minutes to hours, to measure the refraction with the Snellen test card and trial lenses. With the retinoscope, however, it can be determined in a fraction of a second. By the

1 Herman Snellen (1835-1908). Celebrated Dutch ophthalmologist, professor of ophthalmology in the University of Utrecht and director of the Netherlandic Eye Hospital. The present standards of visual acuity were proposed by him, and his test types became the model for those now in use.

20 Simultaneous Retinoscopy

former method it would be impossible, for instance, to get any information about the refraction of a baseball player at the moment he swings for the ball, at the moment he strikes it, and at the moment after he strikes it. But with the retinoscope it is quite easy to determine whether his vision is normal, or whether he is myopic, hypermetropic, or astigmatic, when he does these things; and if any errors of refraction are noted, one can guess their degree pretty accurately by the rapidity of the movement of the shadow.

With the Snellen test card and trial lenses conclusions must be drawn from the patient's statements as to what he sees; but the patient often becomes so worried and confused during the examination that he does not know what he sees, or whether different glasses make his sight better or worse; and, moreover, visual acuity is not reliable evidence of the state of the refraction. One patient with two diopters of myopia may see twice as much as another with the same error of refraction. The evidence of the test card is, in fact,

entirely subjective; that of the retinoscope is entirely objective, depending in no way upon the statements of the patient.

In short, while the testing of the refraction by means of the Snellen test card and trial lenses requires considerable time, and can be done only under certain artificial conditions, with results that are not always reliable, the retinoscope can be used under all sorts of normal and abnormal conditions on the eyes both of human beings and the lower animals; and the results, when it is used properly, can always be depended upon. This means that it must not be brought nearer to the eye than six feet; otherwise the subject will be made nervous, the refraction, for reasons which will be ex-

Retinoscope Reveals New Facts 21

plained later, will be changed, and no reliable observations will be possible. In the case of animals it is often necessary to use it at a much greater distance.

For thirty years I have been using the retinoscope to study the refraction of the eye. With it I have examined the eyes of tens of thousands of school children, hundreds of infants and thousands of animals, including cats, dogs, rabbits, horses, cows, birds, turtles, reptiles and fish. I have used it when the subjects were at rest and when they were in motion - also when I myself was in motion; when they were asleep and when they were awake or even under ether and chloroform. I have used it in the daytime and at night, when the subjects were comfortable and when they were excited; when they were trying to see and when they were not; when they were lying and when they were telling the truth; when the eyelids were partly closed, shutting off part of the area of the pupil, when the pupil was dilated, and also when it was contracted to a pin-point; when the eye was oscillating from side to side, from above downward and in other directions. In this way I discovered many facts which had not previously been known, and which I was quite unable to reconcile with the orthodox teachings on the subject. This led me to undertake the series of experiments already alluded to. The results were in entire harmony with my previous observations, and left me no choice but to reject the entire body of orthodox teaching about accommodation and errors of refraction. But before describing these experiments I must crave the readers patience while I present a resume of the evidence upon which the accepted views of accommodation are based. This evidence, it seems to me, is as

22 Simultaneous Retinoscopy

strong an argument as any I could offer against the doctrine that the lens is the agent of accommodation, while an understanding of the subject is necessary to an understanding of my experiments.

CHAPTER III

EVIDENCE FOR THE ACCEPTED THEORY OF
ACCOMMODATION

THE power of the eye to change its focus for vision at different distances has puzzled the scientific mind ever since Kepler¹ tried to explain it by supposing a change in the position of the crystalline lens. Later on every imaginable hypothesis was advanced to account for it. The idea of Kepler had many supporters. So also had the idea that the change of focus was effected by a lengthening of the eyeball. Some believed that the contractive power of the pupil was sufficient to account for the phenomenon, until the fact was established, by the operation for the removal of the iris, that the eye accommodated perfectly without this part of the visual mechanism. Some, dissatisfied with all these theories, discarded them all, and boldly asserted that no change of focus took place,² a view which was conclusively disproven when the invention of the ophthalmoscope made it possible to see the interior of the eye.

The idea that the change of focus might be brought about by a change in the form of the lens appears to have been first advanced, according to Landolt,³ by the

1 Johannes Kepler (1571-1630). German theologian, astronomer and physicist. Many facts of physiological optics were either discovered, or first clearly stated, by him.

2 Donders: *On the Anomalies of Accommodation and Refraction of the Eye*. English translation by Moore, 1864, p. 10. Frans Cornelis Donders (1818-1889) was professor of physiology and ophthalmology at the University of Utrecht, and is ranked as one of the greatest ophthalmologists of all time.

3 Edmund Landolt (1846-) Swiss ophthalmologist who settled in Paris in 1874, founding an eye clinic which has attracted many students.

23

24 Accepted Theory of Accommodation

Jesuit, Scheiner (1619). Later it was put forward by Descartes (1637). But the first definite evidence in support of the theory was presented by Dr. Thomas Young in a paper read before the Royal Society in 1800.¹ "He adduced reasons," says Donders, "which, properly under

stood, should be taken as positive proofs."² At the time, however, they attracted little attention.

About half a century later it occurred to Maximilian Langenbeck³ to seek light on the problem by the aid of

¹ On the Mechanism of the Eye, Phil. Tr. Roy. Soc., London, 1801.

² On the Anomalies of Accommodation and Refraction of the Eye, pp. 10-11.

³ Maximilian Adolf Langenbeck (1518-1877). Professor of anatomy, surgery and ophthalmology at Gottingen, from 1846 to 1851. Later settled in Hanover.

Studies of the Images of Purkinje 25

what are known as the images of Purkinje.¹ If a small bright light, usually a candle, is held in front of and a little to one side of the eye, three images are seen: one bright and upright; another large, but less bright, and also upright; and a third small, bright and inverted. The first comes from the cornea, the transparent covering of the iris and pupil, and the other two from the lens, the upright one from the front and the

inverted one from the back. The corneal reflection was known to the ancients, although its origin was not discovered till later; but the two reflections from the lens were first observed in 1823 by Purkinje; whence the trio of images is now associated with his name. Langenbeck examined these images with the naked eye, and reached the conclusion that during accommodation the middle one became smaller than when the eye was at rest. And since an image reflected from a convex surface is diminished in proportion to the convexity of that surface, he concluded that the front of the lens became more convex when the eye adjusted itself for near vision. Donders repeated the experiments of Langenbeck, but was unable to make any satisfactory observations. He predicted, however, that if the images were examined with a magnifier they would "show with certainty" whether the form of the lens changed during accommodation. Cramer,² acting on this suggestion, examined the images as magnified from ten to twenty times, and thus convinced himself that the one reflected from the front of the lens became considerably smaller during accommodation.

1 Johannes Evangelista von Purkinje (1787-1869). Professor of physiology at Breslau and Prague, and the discoverer of many important physiological facts.

2 Antonie C. Cramer (1822-1855). Dutch ophthalmologist.

26 Accepted Theory of Accommodation

Subsequently Helmholtz, working independently, made a similar observation, but by a somewhat different method. Like Donders, he found the image obtained by the ordinary methods on the front of the lens very unsatisfactory, and in his "Handbook of Physiological Optics" he describes it as being "usually so blurred that the form of the flame cannot be definitely distinguished."¹ So he placed two lights, or one doubled by reflection from a mirror, behind a screen in which were two small rectangular openings, the whole being so arranged that the lights shining through the openings of the screen formed two: images on each of the reflecting surfaces. During accommodations, it seemed to him that the two images on the front of the lens became smaller and approached each other, while on the return of the eye to a state of rest they grew larger again and separated. This change, he said, could be seen "easily and distinctly."² The observations of Helmholtz regarding the behavior of the lens in accommodation, published about the middle of the last century, were soon accepted as facts, and have ever since been stated as such in every text-book dealing with the subject.

"We may say," writes Landolt, "that the discovery of the part played by the crystalline lens in the act of accommodation is one of the finest achievements of medical physiology, and the theory of its working is certainly one of the most firmly established; for not only have "savans" furnished lucid and mathematical proofs of its correctness, but all other theories which have been advanced as explaining accommodation have been easily

1 Handbuch der physiologischen Optik, edited by Nagel, 1909-11, vol. i, p. 121.

2 Ibid. vol. i, p. 122.

and entirely overthrown.... The fact that the eye is accommodated for near vision by an increase in the curvature of its crystalline lens, is, then, incontestably proved."¹

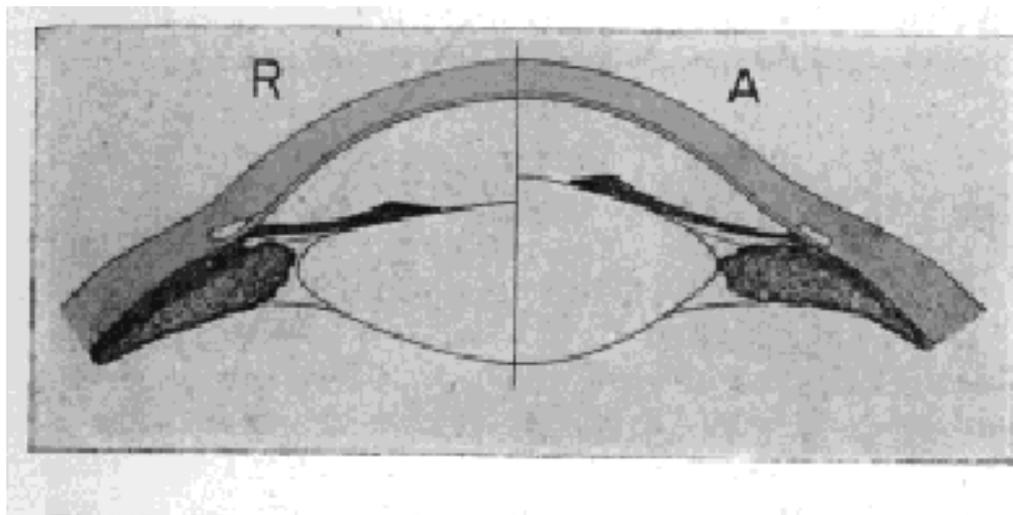

Fig. 10. Diagram by Which Helmholtz Illustrated His Theory of Accommodation

R is supposed to be the resting state of the lens, in which it is adjusted for distant vision. In A the suspensory ligament is supposed to have been relaxed through the contraction of the ciliary muscle, permitting the lens to bulge forward by virtue of its own elasticity.

"The question was decided," says Tscherning, "by the observation of the changes of the images of Purkinje during accommodation, which prove that accommodation is effected by an increase of curvature of the anterior surface of the crystalline lens."²

Marius Hans Erik Tscherning (1854 -) is a Danish ophthalmologist who

for twenty-five years was co-director and director of the ophthalmological

laboratory of the Sorbonne. Later he became professor of ophthalmology in

the University of Copenhagen.

Fig. 11. Thomas Young (1773-1829)

English physician and man of science who was the first to present a serious argument in support of the view that accommodation is brought about by the agency of the lens.

"The greatest thinkers," says Cohn, "have mastered a host of difficulties in discovering this arrangement,

and it is only in very recent times that its processes have been clearly and perfectly set forth in the works of Sanson, Helmholtz, Brucke, Hensen and Volckers."¹

Huxley refers to the observations of Helmholtz as the "facts of adjustment with which all explanations of that process must accord,"² and Donders calls his theory the "true principle of accommodation."³

Arlt, who had advanced the elongation theory and believed that no other was possible, at first opposed the conclusions of Cramer and Helmholtz,⁴ but later accepted them.⁵

Yet in examining the evidence for the theory we can only wonder at the scientific credulity which could base such an important department of medical practice as the treatment of the eye upon such a mass of contradictions. Helmholtz, while apparently convinced of the correctness of his observations indicating a change of form in the lens during accommodation, felt himself unable to speak with certainty of the means by which the supposed change was effected,³ and strangely enough the question is still being debated. Finding, as he states, "absolutely nothing but the ciliary muscle to which accommodation could be attributed,"⁷ Helmholtz concluded that the changes which he thought he had observed in the curvature of the lens must be effected by the action of this muscle; but he was unable to offer any satisfac-

30 Accepted Theory of Accommodation

tory theory of the way it operated to produce these results, and he explicitly stated that the one he suggested possessed only the character of probability. Some of his disciples, "more loyal than the king," as Tscherning has pointed out, "have proclaimed as certain what he himself with much reserve explained as probable,"¹ but there has been no such unanimity of acceptance in this case as in that of the observations regarding the behavior of the images reflected from the lens. No one except the present writer, so far as I am aware, has ventured to question that the ciliary muscle is the agent of accommodation; but as to the mode of its

operation there is generally felt to be much need for more light. Since the lens is not a factor in accommodation, it is not strange that no one was able to find out how it changed its curvature. It "is" strange, however, that these difficulties have not in any way disturbed the universal belief that the lens does change.

When the lens has been removed for cataract the patient usually appears to lose his power of accommodation, and not only has to wear a glass to replace the lost part, but has to put on a stronger glass for reading. A minority of these cases, however, after they become accustomed to the new condition, become able to see at the near-point without any change in their glasses. The existence of these two classes of cases has been a great stumbling block to ophthalmology. The first and more numerous appeared to support the theory of the agency of the lens in accommodation; but the second was hard to explain away, and constituted at one time, as Dr. Thomas Young observed, the "grand objection" to this idea. A number of these cases of apparent change of focus

1 Physiologic Optics, p. 166.

Herman- Ludwig Ferdinand von Helmholtz (1821-1894)

whose observations regarding the behavior of images reflected from the front of the lens are supposed to have demonstrated that the curvature of this body changes during accommodation.

31

32 Accepted Theory of Accommodation

in the lensless eye having been reported to the Royal Society by competent observers, Dr. Young, before bringing forward his theory of accommodation, took the trouble to examine some of them, and considered himself justified in concluding that an error of observation had been made. While convinced, however, that in such eyes the "actual focal distance is totally unchangeable," he characterized his own evidence in support of this view as only "tolerably satisfactory." At a later period Donders made some investigations from which he concluded that "in aphakial not the slightest trace of accommodative power remains."² Helmholtz expressed similar views, and von Graefe, although he observed a "slight residuum" of accommodative power in lensless eyes, did not consider it sufficient to discredit the theory of Cramer and Helmholtz. It might be due, he said, to the accommodative action of the iris, and possibly also to a lengthening of the visual axis through the action of the external muscles.³

For nearly three-quarters of a century the opinions of these masters have echoed through ophthalmological literature. Yet it is to-day a perfectly well-known and undisputed fact that many persons, after the removal of the lens for cataract, are able to see perfectly at different distances without any change in their glasses. Every ophthalmologist of any experience has seen cases of this kind, and many of them have been reported in the literature.

In 1872, Professor Forster of Breslau, reported⁴ a

4 *Klin. Monatsbl. f. Augenh.*, Erlangen, 1872, vol. x, p. 39, et seq.

Not To Be Disputed 33

series of twenty-two cases of apparent accommodation in eyes from which the lens had been removed for cataract. The subjects ranged in age from eleven to seventyfour years, and the younger ones had more accommodative power than the elder. A year later Woinow of Moscow¹ reported eleven cases, the subjects being from twelve to sixty years of age. In 1869 and 1870, respectively, Loring reported² to the New York Ophthalmological Society and the American Ophthalmological Society the case of a young woman of eighteen who, without any change in her glasses, read the twenty line on the Snellen test card at twenty feet and also read diamond type at from five inches to twenty. On October 8, 1894, a patient of Dr. A. E. Davis who appeared to accommodate perfectly without a lens consented to go before the New York Ophthalmological Society. "The members," Dr. Davis reports,³ "were divided in their opinion as to how the patient was able to accommodate for the nearpoint with his distance glasses on"; but the fact that he could see at this point without any change in his glasses was not to be disputed.

The patient was a chef, forty-two years old, and on January 27, 1894, Dr. Davis had removed a black cataract from his right eye, supplying him at the same time with the usual outfit of glasses, one to replace the lens, for distant vision, and a stronger one for reading. In October he returned, not because his eye was not doing well, but because he was afraid he might be "straining" it. He had discarded his reading glasses after a few weeks, and had since been using only his distance glasses. Dr.

3 Davis: *Accommodation in the Lensless Eye*, Reports of the Manhattan Eye and Ear Hospital, Jan., 1895. The article gives a review of the whole subject.

34 Accepted Theory of Accommodation

Davis doubted the truth of his statements, never having seen such a case before, but found them, upon investigation, to be quite correct. With his lensless eye and a convex glass of eleven and a half diopters, the patient read the ten line on the test card at twenty feet, and with the same glass, and without any change in its position, he read fine print at from fourteen to eighteen inches. Dr. Davis then presented the case to the Ophthalmological Society but, as has been stated, he obtained no light from that source. Four months later, February 4, 1895, the patient still read 20/10 at the distance and his range at the near-point had increased so that he read diamond type at from eight to twenty-two and a half inches. Dr. Davis subjected him to

numerous tests, and though unable to find any explanation for his strange performances, he made some interesting observations. The results of the tests by which Donders satisfied himself that the lensless eye possessed no accommodative power were quite different from those reported by the Dutch authority, and Dr. Davis therefore concluded that these tests were "wholly inadequate to decide the question at issue." During accommodation the ophthalmometer¹ showed that the corneal curvature was changed and that the cornea moved forward a little. Under scopolamine, a drug sometimes used instead of atropine to paralyze the ciliary muscle (1/10 per cent solution every five minutes for thirty-five minutes, followed by a wait of half an hour), these changes took place as before; they also took place when the lids were held up. With the possible influence of lid pressure and of the ciliary muscle eliminated, therefore, Dr. Davis felt himself bound to conclude that the changes "must

1 An instrument for measuring the curvature of the cornea.

Another Puzzling Case 35

have been produced by the action of the external muscles." Under scopolamine, also, the man's accommodation was only slightly affected, the range at the nearpoint being reduced only two and a half inches.

The ophthalmometer further showed the patient to have absolutely no astigmatism. It had showed the same thing about three months after the operation, but three and a half weeks after it he had four and a half diopters.

Seeking further light upon the subject Dr. Davis now subjected to similar tests a case which had previously been reported by Webster in the "Archives of Pediatrics." ¹ The patient had been brought to -Dr. Webster at the age of ten with double congenital cataract. The left lens had been absorbed as the result of successive needlings, leaving only an opaque membrane, the lens capsule, while the right, which had not been interfered with, was sufficiently transparent around the edge to admit of useful vision. Dr. Webster made an opening in the membrane filling the pupil of the left eye, after which the vision of this eye, with a glass to replace the lens, was about equal to the vision of the right eye without a glass. For this reason Dr. Webster did not think it necessary to give the patient distance glasses, and supplied him with reading glasses only - plane glass for the-right eye and convex 16D for the left. On March 14, 1893, he returned and stated that he had been wearing his reading glasses all the time. With this glass it was found that he could read the twenty line of the test card at twenty feet, and read diamond type easily at fourteen inches. Subsequently the right lens was removed, after which no accommodation was observed in this eye. Two years later,

1 Nov., 1893, p. 932.

36 Accepted Theory of Accommodation

March 16, 1895, he was seen by Dr. Davis, who found that the left eye now had an accommodative range of from ten to eighteen inches. In this case no change was observed in the cornea. The results of the

Donders tests were similar to those of the earlier case, and under scopolamine the eye accommodated as before, but not quite so easily. No accommodation was observed in the right eye.

These and similar cases have been the cause of great embarrassment to those who feel called upon to reconcile them with the accepted theories. With the retinoscope the lensless eye can be seen to accommodate; but the theory of Helmholtz has dominated the ophthalmological mind so strongly that even the evidence of objective tests was not believed. The apparent act of accommodation was said not to be real, and many theories, very curious and unscientific, have been advanced to account for it. Davis is of the opinion that "the slight change in the curvature of the cornea, and its slight advancement observed in some cases, may, in those cases, account for some of the accommodative power present, but it is such a small factor that it may be eliminated entirely, since in some of the most marked cases of accommodation in aphakial eyes no such changes have been observed."

The voluntary production of astigmatism is another stumbling block to the supporters of the accepted theories, as it involves a change in the shape of the cornea, and such a change is not compatible with the idea of an "inextensible"¹ eyeball. It seems to have given them less trouble, however, than the accommodation of the lensless

¹ Inasmuch as the eye is inextensible, it cannot adapt itself for the perception of objects situated at different distances by increasing the length of its axis, but only by increasing the refractive power of its lens. - De Schweinitz: Diseases of the Eye, eighth edition, 1916, pp. 35-36.

Voluntary Production of Astigmatism 37

eye, because fewer of these cases have been observed and still fewer have been allowed to get into the literature. Some interesting facts regarding one have fortunately been given by Davis, who investigated it in connection with the corneal changes noted in the lensless eye. The case was that of a house surgeon at the Manhattan Eye and Ear Hospital, Dr. C. H. Johnson. Ordinarily this gentleman had half a diopter of astigmatism in each eye; but he could, at will, increase this to two diopters in the right eye and one and a half in the left. He did this many times, in the presence of a number of members of the hospital staff, and also did it when the upper lids were held up, showing that the pressure of the lids had nothing to do with the phenomenon. Later he went to Louisville, and here Dr. J. M. Ray, at the suggestion of Dr. Davis, tested his ability to produce astigmatism under the influence of scopolamine (four instillations, 1/5 per cent solution). While the eyes were under the influence of the drug the astigmatism still seemed to increase, according to the evidence of the ophthalmometer, to one and a half diopters in the right eye and one in the left. From these facts, the influence of the lids and of the ciliary muscle having been eliminated, Dr. Davis concluded that the change in the cornea was "brought about mainly by the external muscles." What explanation others offer for such phenomena I do not know.

CHAPTER IV

THE TRUTH ABOUT ACCOMMODATION AS DEMONSTRATED BY EXPERIMENTS ON THE EYE MUSCLES OF FISH, CATS, DOGS, RABBITS AND OTHER ANIMALS

THE function of the muscles on the outside of the eyeball, apart from that of turning the globe in its socket, has been a matter of much dispute; but after the supposed demonstration by Helmholtz that accommodation depends upon a change in the curvature of the lens, the possibility of their being concerned in the adjustment of the eye for vision at different distances, or in the production of errors of refraction, was dismissed as no longer worthy of serious consideration. "Before physiologists were acquainted with the changes in the dioptic system,"¹ says Donders, "they often attached importance to the external muscles in the production of accommodation. Now that we know that accommodation depends on a change of form in the lens this opinion seems scarcely to need refutation." He states positively that "many instances occur where the accommodation is wholly destroyed by paralysis, without the external muscles being the least impeded in their action," and also that "some cases are on record of paralysis of all or nearly all of the muscles of the eye, and of deficiency of the same, without diminution of the power of accommodation."²

If Donders had not considered the question settled, he

1 The refractive system.

2 On the Anomalies of Accommodation and Refraction of the Eye, p. 22.

38

The External Muscles of the Eyeball 39

might have inquired more carefully into these cases, and if he had, he might have been less dogmatic in his statements; for, as has been pointed out in the preceding chapter, there are plenty of indications that the contrary is the case. In my own experiments upon the extrinsic eye muscles of fish, rabbits, cats, dogs and other animals, the demonstration seemed to be complete that in the eyes of these animals accommodation depends wholly upon the action of the extrinsic muscles and not at all upon the agency of the lens. By the manipulation of these muscles I was able to produce or prevent accommodation at will, to produce myopia, hypermetropia and astigmatism, or to prevent these conditions. Full details of these experiments will be found in the "Bulletin of the New York Zoological Society" for November, 1914, and in the "New York Medical Journal" for May 8, 1915; and May 18, 1918; but for the benefit of those who have not the time or inclination to read these papers, their contents are summarized below.

There are six muscles on the outside of the eyeball, four known as the "recti" and two as the "obliques." The obliques form an almost complete belt around the middle of the eyeball, and are known, according to

their position, as "superior" and "inferior." The recti are attached to the sclerotic, or outer coat of the eyeball, near the front, and pass directly over the top, bottom and sides of the globe to the back of the orbit, where they are attached to the bone round the edges of the hole through which the optic nerve passes. According to their position, they are known as the "superior," "inferior," "internal" and "external" recti.- The obliques are the muscles of accommodation; the recti are concerned in the production of hypermetropia and astigmatism.

40 Accommodation: Experiments on Animals

In some cases one of the obliques is absent or rudimentary, but when two of these muscles were present and active, accommodation, as measured by the objective test

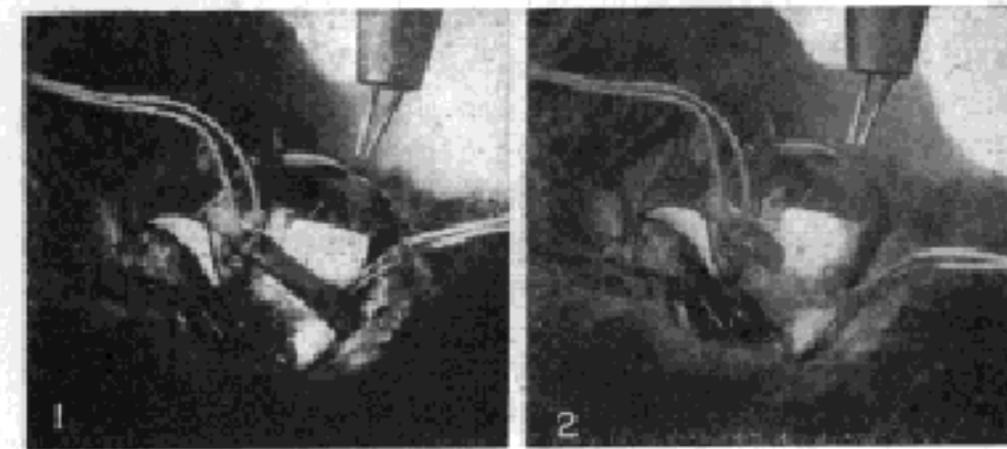

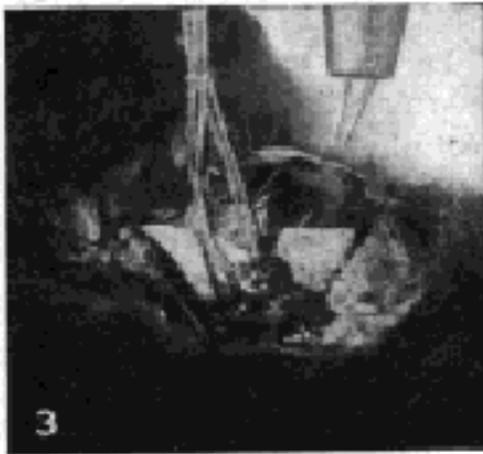

Fig. 13. Demonstration Upon the Eye of a Rabbit that the Inferior Oblique Muscle is an Essential Factor in Accommodation

No. 1. - The inferior oblique muscle has been exposed and two sutures are attached to it. Electrical stimulation of the eyeball produces accommodation as demonstrated by simultaneous retinoscopy.

No. 3. - The muscle has been sewed together. Electrical stimulation produces normal accommodation.

of retinoscopy, was always produced by electrical stimulation either of the eyeball, or of the nerves of accommodation near their origin in the brain. It was also pro-

Oblique Muscles Inactive: No Accommodation

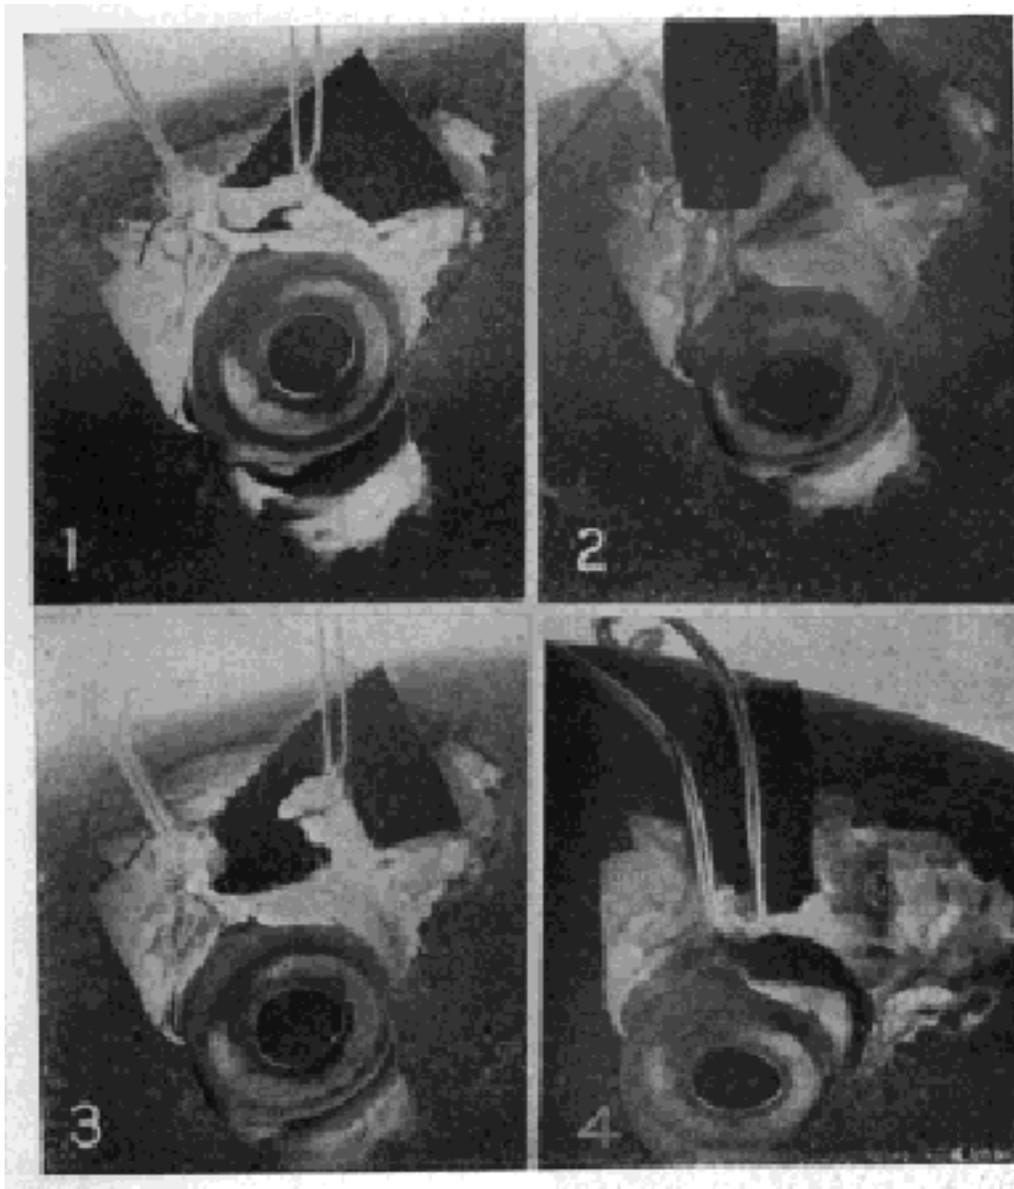

Fig. 14. Demonstration Upon the Eye of a Carp That the Superior Oblique Muscle Is Essential to Accommodation.

No. 1. - The superior oblique is lifted from the eyeball by two sutures, and the retinoscope shows no error

of refraction. No. 2. - Electrical stimulation produces accommodation, as determined by the retinoscope. No. 3. - The muscle has been cut. Stimulation of the eyeball with electricity fails to produce accommodation. No. 4. - The divided muscle has been reunited by tying the sutures. Accommodation follows electrical stimulation as before.

42 Accommodation: Experiments on Animals

duced by any manipulation of the obliques whereby their pull was increased. This was done by a tucking operation of one or both muscles, or by an advancement of the

No. 3. - Upward pull in the plane of the iris. Mixed astigmatism is produced.

point at which they are attached to the sclerotic. When; one or more of the recti had been cut, the effect of operations increasing the pull of the obliques was intensified.

The Extrinsic Muscles in Refractive Errors 43

After one or both of the obliques had been cut across, or after they had been paralyzed by the injection of atropine deep into the orbit, accommodation could never be

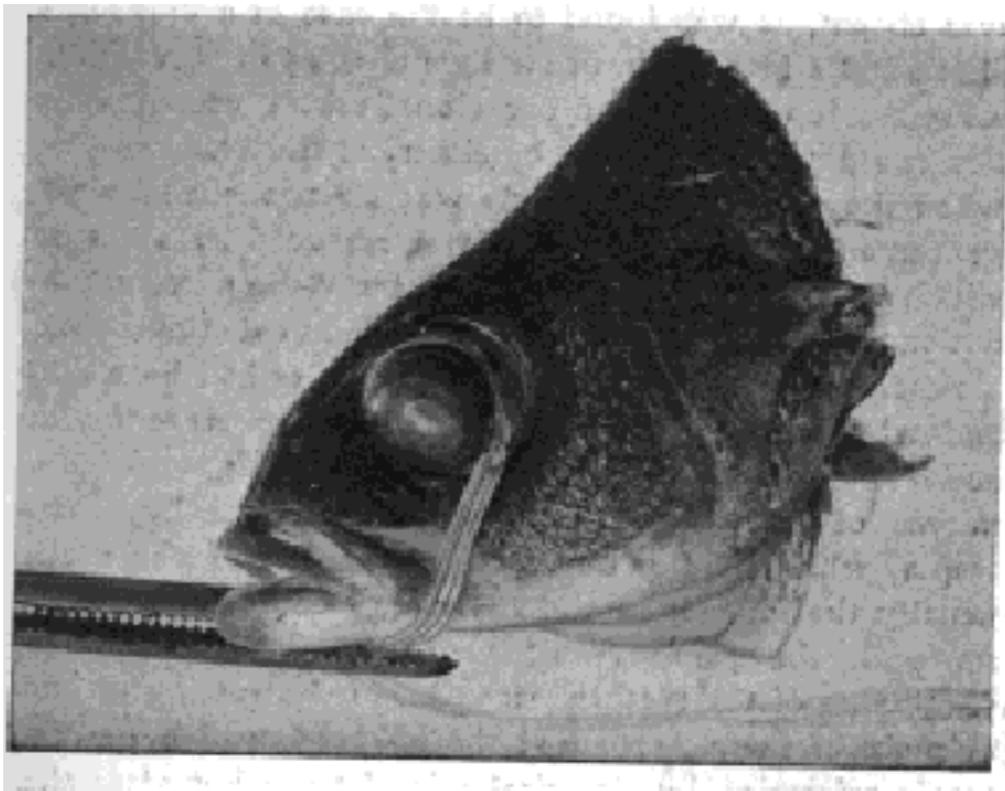

Fig. 16. Demonstration Upon the Eye of a Fish That the Production of Myopic and Hypermetropic Refraction Is Dependent Upon the Action of the Extrinsic Muscles.

Suture tied to the insertion of the superior rectus muscle. By means of strong traction upon the suture the eyeball is turned in its socket, and by tying the thread to a pair of fixation forceps which grasp! the lower jaw, it is maintained in this position. A high degree of mixed astigmatism is produced, as demonstrated by simultaneous retinoscopy. When the superior oblique is divided the myopic part of the astigmatism disappears, and when the inferior rectus is cut the hypermetropic part disappears, and the eye becomes normal - adjusted for distant vision - although the same amount of traction is maintained. It is evident that these muscles are essential factors in the production of myopia and hypermetropia.

44 Accommodation: Experiments on Animals

produced by electrical stimulation; but after the effects of the atropine had passed away, or a divided muscle had been sewed together, accommodation followed electrical stimulation just as usual. Again when one oblique muscle was absent, as was found to be the case in a dogfish, a shark and a few perch, or rudimentary, as in all cats observed, a few fish and an occasional rabbit, accommodation could not be produced by electrical stimulation. But when the rudimentary muscle was strengthened by advancement, or the absent one was replaced by a suture which supplied the necessary countertraction, accommodation could always be produced by electrical stimulation.

After one or both of the oblique muscles had been cut, and while two or more of the recti were present and active,¹ electrical stimulation of the eyeball, or of the nerves of accommodation, always produced hypermetropia, while by the manipulation of one of the recti, usually the inferior or the superior, so as to strengthen its pull, the same result could be produced. The paralyzing of the recti by atropine, or the cutting of one or more of them, prevented the production of hypermetropic refraction by electrical stimulation; but after the effects of the atropine had passed away, or after a divided muscle had been sewed together, hypermetropia was produced as usual by electrical stimulation.

It should be emphasized that in order to paralyze either the recti muscles, or the obliques, it was found necessary to inject the atropine far back behind the eyeball with a hypodermic needle. This drug is supposed to paralyze the accommodation when dropped into the eyes of human

¹ In many animals, notably in rabbits, the internal and external recti are either absent or rudimentary, so that, practically, in such cases, there are only two recti, just as there are only two obliques. In others, as in many fish, the internal rectus is negligible.

Production of Astigmatism 45

beings or animals, but in all of my experiments it was found that when used in this way it had very little effect upon the power of the eye to change its focus.

Astigmatism was usually produced in combination

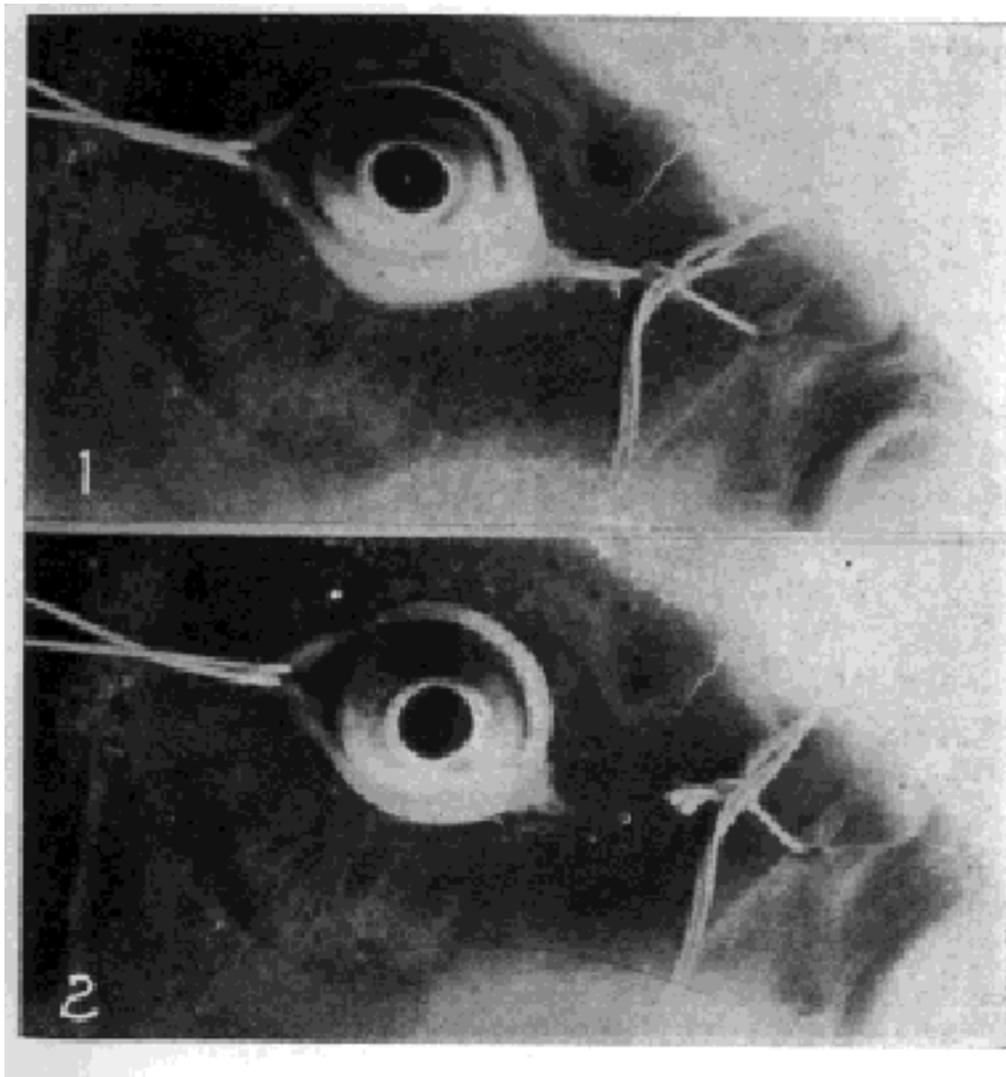

Fig. 17.

No. 1. - Production of mixed astigmatism in the eye of a carp by pulling strings attached to the conjunctiva in opposite directions. Note the oval shape of the front of the eyeball.

No. 2. - With the cutting of the strings the eyeball returns to its normal shape, and the refraction becomes normal.

46 Accommodation: Experiments on Animals

with myopic or hypermetropic refraction. It was also produced by various manipulations of both the oblique and recti muscles. Mixed astigmatism, which is a combination of myopic with hypermetropic refraction, was

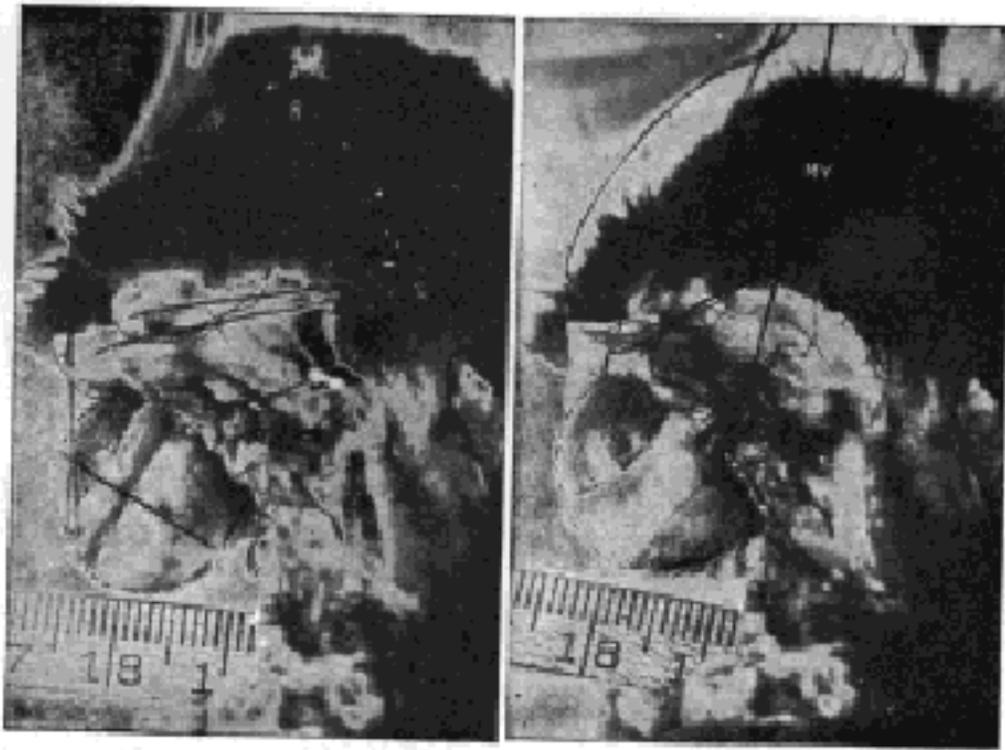

Fig. 18. Demonstration Upon the Eyeball of a Rabbit That the
Obliques Lengthen the Visual Axis in Myopia

R, rest. The eyeball is of normal length and emmetropic - that is, perfectly adjusted for distant vision. My, myopia. The pull of the oblique muscles has been strengthened by advancement and the retinoscope shows that myopia has been produced. It can easily be noted that the eyeball is longer. It was impossible to avoid some movement of the head between the taking of the two pictures as a result of the manipulation of the strings, but the rule shows that the focus of the camera was not appreciably changed by such movements.

always produced by traction on the insertion of the superior or inferior rectus in a direction parallel to the plane of the iris, so long as both obliques were present and active; but if either or both of the obliques had been cut,

The Recti in Hypermetropia 47

the myopic part of the astigmatism disappeared. Similarly after the superior or the inferior rectus had been cut the hypermetropic part of the astigmatism disappeared. Advancement of the two obliques, with advancement of the superior and inferior recti, always produced mixed astigmatism.

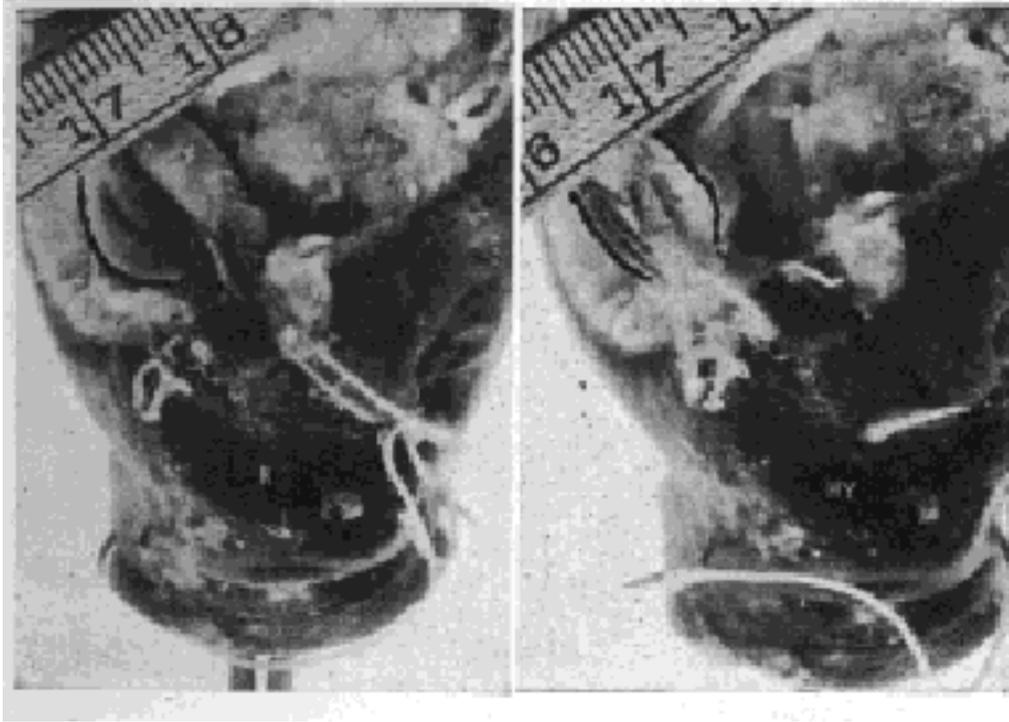

Fig. 19. Demonstration Upon the Eye of a Carp That the
Recti Shorten the Visual Axis in Hypermetropia

R, rest. The eyeball is of normal length and emmetropic. Hy, hypermetropia. The pull of the external and internal recti has been strengthened by advancement, and the retinoscope shows that hypermetropia has been produced. It may easily be noted that the eyeball is shorter. The rule shows that the focus of the camera was not appreciably changed between the taking of the two pictures.

Eyes from which the lens had been removed, or in which it had been pushed out of the axis of vision, responded to electrical stimulation precisely as did the normal eye, so long as the muscles were active; but

48 Accommodation: Experiments on Animals

when they had been paralyzed by the injection of atropine deep into the orbit, electrical stimulation had no effect on the refraction.

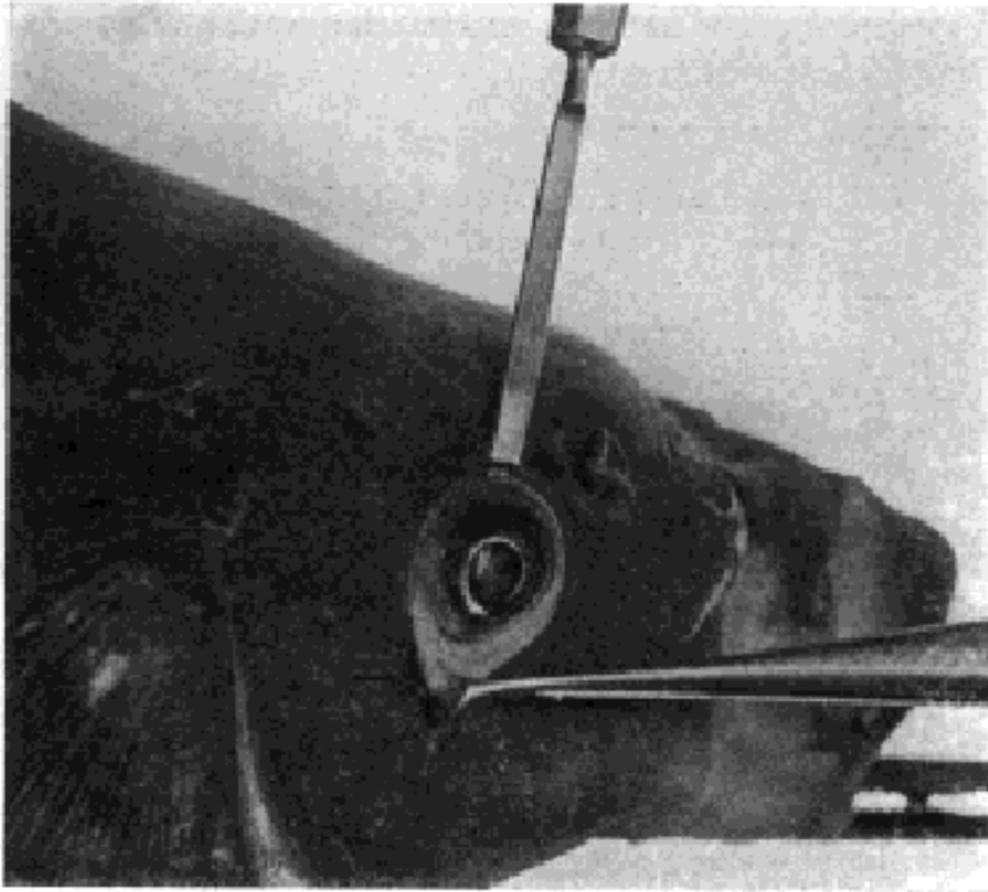

Fig. 20. Lens Pushed Out of the Axis of Vision

In this experiment on the eye of a carp the lens was pushed out of the axis of vision. Accommodation took place after this displacement just as it did before. Note the point of the knife in the pupil in front of the lens.

In one experiment the lens was removed from the right eye of a rabbit, the refraction of each eye having first been tested by retinoscopy and found to be normal. The wound was then allowed to heal. Thereafter, for a

Accommodation in Aphakia 49

period extending from one month to two years, electrical stimulation always produced accommodation in the lensless eye precisely to the same extent as in the eye which

Fig. 21. Rabbit With Lens Removed

The animal was exhibited at a meeting of the Ophthalmological Section of the American Medical Association, held in Atlantic City, and was examined by a number of ophthalmologists present, all of whom testified that electrical stimulation of the eyeball produced accommodation, or myopic refraction, precisely as in the normal eye.

had a lens. The same experiment with the same result was performed on a number of other rabbits, on dogs and on fish. The obvious conclusion is that the lens is not a factor in accommodation.

50 Accommodation: Experiments on Animals

In most text-books on physiology it is stated that accommodation is controlled by the third cranial nerve, which supplies all the muscles of the eyeball except the superior oblique and the external rectus; but the fourth cranial nerve, which supplies only the superior oblique, was found in these experiments to be just as much a nerve of accommodation as the third. When either the third or the fourth nerve was stimulated with electricity near its point of origin in the brain accommodation al-

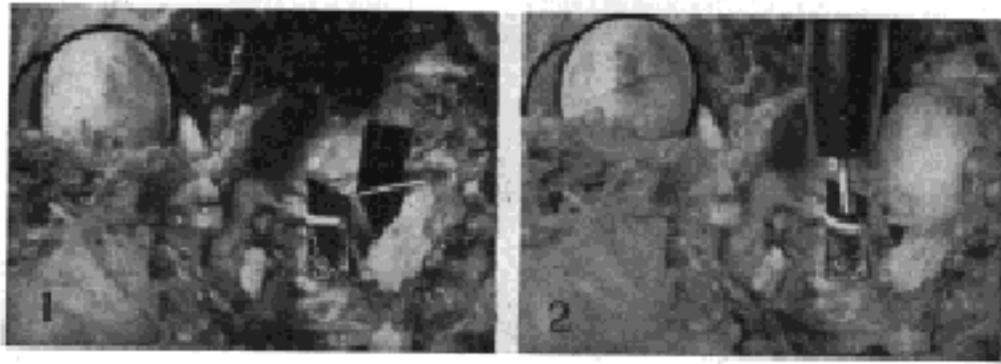

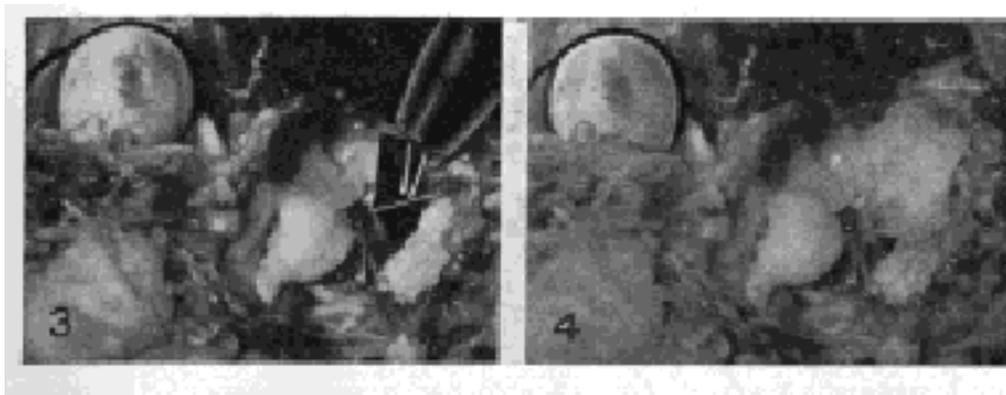

Fig. 22. Experiment Upon the Eye of a Cat Demonstrating That the Fourth Nerve, Which Supplies Only the Superior Oblique Muscle, Is Just as Much a Nerve of Accommodation As the Third, and That the Superior Oblique Muscle Which It Supplies Is a Muscle of Accommodation.

No. 1. - Both nerves have been exposed near their origin in the brain, and a strip of black paper has been inserted beneath each to render it visible. The fourth nerve is the smaller one. The superior oblique muscle has been advanced by a tucking operation, as this muscle is always rudimentary in cats, and unless its pull is strengthened accommodation cannot be produced in these animals. Stimulation of either or both nerves by the faradic current produced accommodation.

No. 2. - When the fourth nerve was covered with cotton soaked in a normal salt solution, the application of the faradic current to the cotton produced accommodation. When the cotton was soaked in a one per cent solution of atropine sulphate in a normal salt solution, such application produced no accommodation, but stimulation of the third nerve did produce it.

The Role of the Fourth Nerve 51

No. 3. When the third nerve was covered with cotton soaked in a normal salt solution, the application of the faradic current to the cotton produced accommodation. When the cotton was soaked with atropine sulphate in a normal salt solution, such application produced no accommodation, but the stimulation of

the fourth nerve did produce it.

No. 4. - When both nerves were covered with cotton soaked in atropine sulphate in a normal salt solution, the application of electricity to the cotton produced no accommodation. When the parts had been washed with a warm salt solution electrical stimulation of either nerve always produced accommodation. The nerves were alternately covered with the atropine-soaked cotton and then washed with the warm saline solution for an hour the electricity being applied in each condition with invariably the same result. Accommodation could never be produced by electrical stimulation when the nerves were paralyzed with the atropine, but always resulted from the stimulation of either or both when they had been washed with the salt solution. The experiment was performed with the same results on many rabbits and dogs.

ways resulted in the normal eye. When the origin of either nerve was covered with a small wad of cotton soaked in a two per cent solution of atropine sulphate in a normal salt solution, stimulation of that nerve produced no accommodation, while stimulation of the unparalyzed nerve did produce it. When the origin of both nerves was covered with cotton soaked in atropine, accommodation could not be produced by electrical stimulation of either or both. When the cotton was removed and the nerves washed with normal salt solution, elec-

52 Accommodation: Experiments on Animals

trical stimulation of either or both produced accommodation just as before the atropine had been applied. This experiment, which was performed repeatedly for more

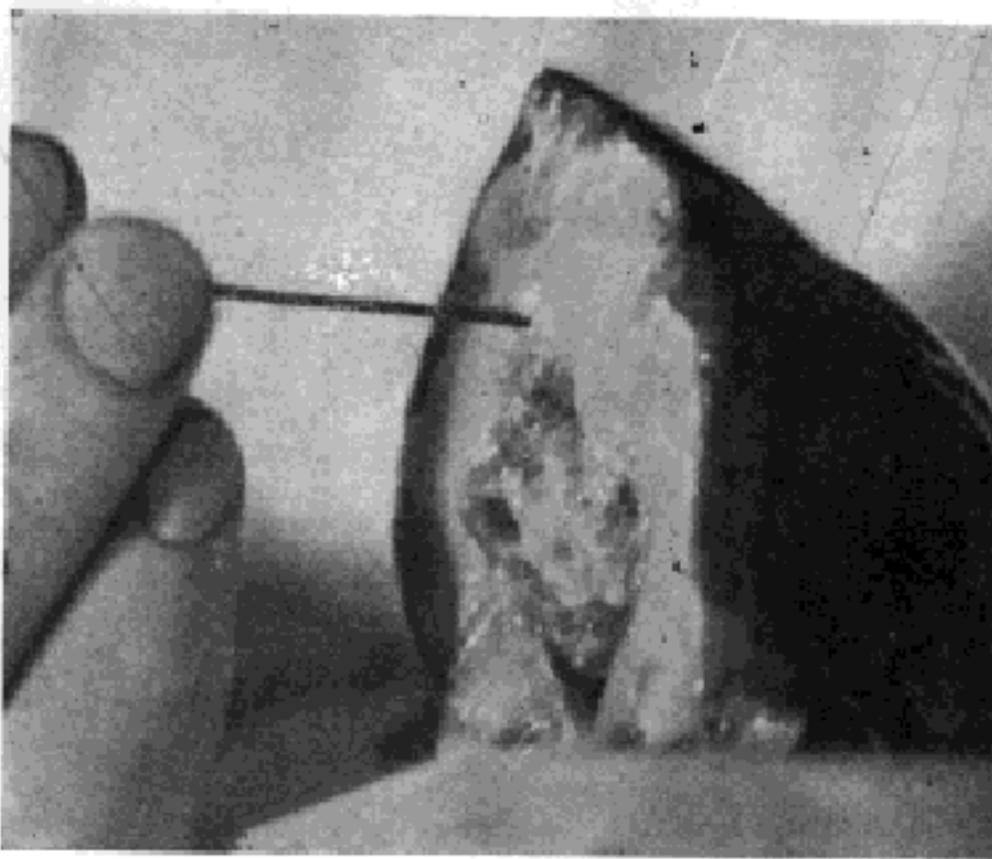

Fig. 23. Pithing a Fish Preparatory to Operating Upon Its Eyes

The object of this operation is to secure greater relaxation of the muscles of the eyes and head, which would work for hours, without external stimulus, if the brain cells were not destroyed by the probe.

than an hour by alternately applying and removing the atropine, not only demonstrated clearly what had not been known before, namely, that the fourth nerve is a nerve of accommodation, but also demonstrated that the

No Room for Doubt 53

superior oblique muscle which is supplied by it is an important factor in accommodation. It was further found that when the action of the oblique muscles was prevented by dividing them, the stimulation of the third nerve produced, not accommodation, but hypermetropia.

In all the experiments all sources of error are believed to have been eliminated. They were all repeated many times and always with the same result. They seemed, therefore, to leave no room for doubt that neither the lens nor any muscle inside the eyeball has anything to do with accommodation, but that the process whereby the eye adjusts itself for vision at different distances is entirely controlled by the action

of the muscles on the outside of the globe.

CHAPTER V

THE TRUTH ABOUT ACCOMMODATION AS DEMONSTRATED BY A STUDY OF IMAGES REFLECTED FROM THE LENS, CORNEA, IRIS AND SCLERA

AS the conclusions to which the experiments described in the preceding chapter pointed were diametrically opposed to those reached by Helmholtz in his study of the images reflected from the front of the lens, I determined to repeat the experiments of the German investigator and find out, if possible, why his results were so different from my own. I devoted four years to this work, and was able to demonstrate that Helmholtz had erred through a defective technique, the image obtained by his method being so variable and uncertain that it lends itself to the support of almost any theory.

I worked for a year or more with the technique of Helmholtz, but was unable to obtain an image from the front of the lens which was sufficiently clear or distinct to be measured or photographed. With a naked candle as the source of light a clear and distinct image could be obtained on the cornea; on the back of the lens it was quite clear; but on the front of the lens it was very imperfect. Not only was it blurred, just as Helmholtz stated, but without any ascertainable cause it varied greatly in size and intensity. At times no reflection could be obtained at all, regardless of the angle of the light to the eye of the subject, or of the eye of the observer to that of the subject. With a diaphragm I got

54

How the Focus Was Changed 55

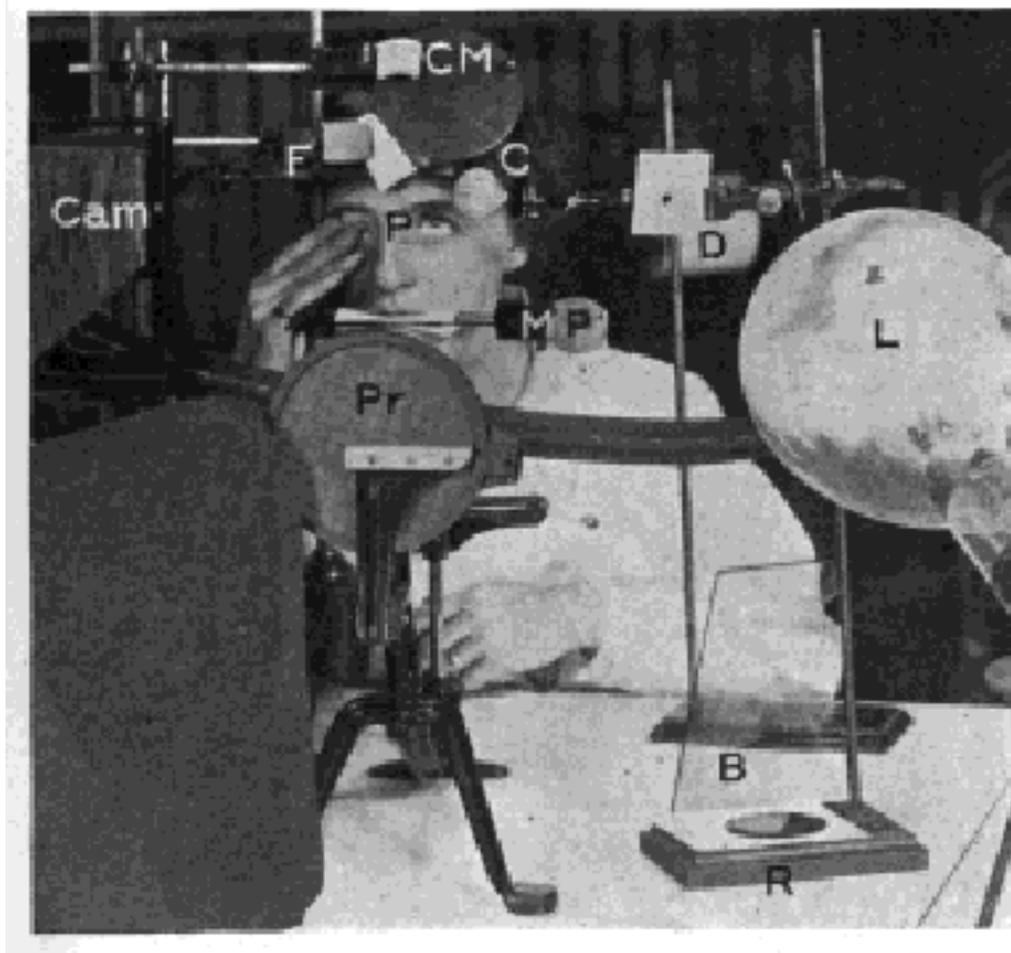

Fig. 24. Arrangements for Photographing Images Reflected

From the Eyeball

CM, concave mirror in which the subject may observe the images reflected from various parts of her eye- C, condenser; D, diaphragm; L, 1000-watt lamp; F, forehead rest; MP, bar which the subject grasps with her teeth for the purpose of holding her head steady- P, plane mirror upon which is pasted a letter of diamond type and in which is reflected a Snellen test card twenty feet behind the subject (the mirror is just above the letter P); CAM, camera; Pr, perimeter used to measure the angle of the light to the eye; R, plane mirror reflecting light from the 1000-watt lamp upon the eye, which otherwise would be in total darkness except for the part from which the highly condensed image of the filament is reflected; B, blue glass screen used to modify the light reflected from the mirror R. When the subject read the bottom line of the Snellen test card reflected in the mirror P her eye was at rest, and when she saw the letter of diamond type distinctly it was accommodated ten diopters, as demonstrated by the retinoscope.

56 Accommodation: Study of Images

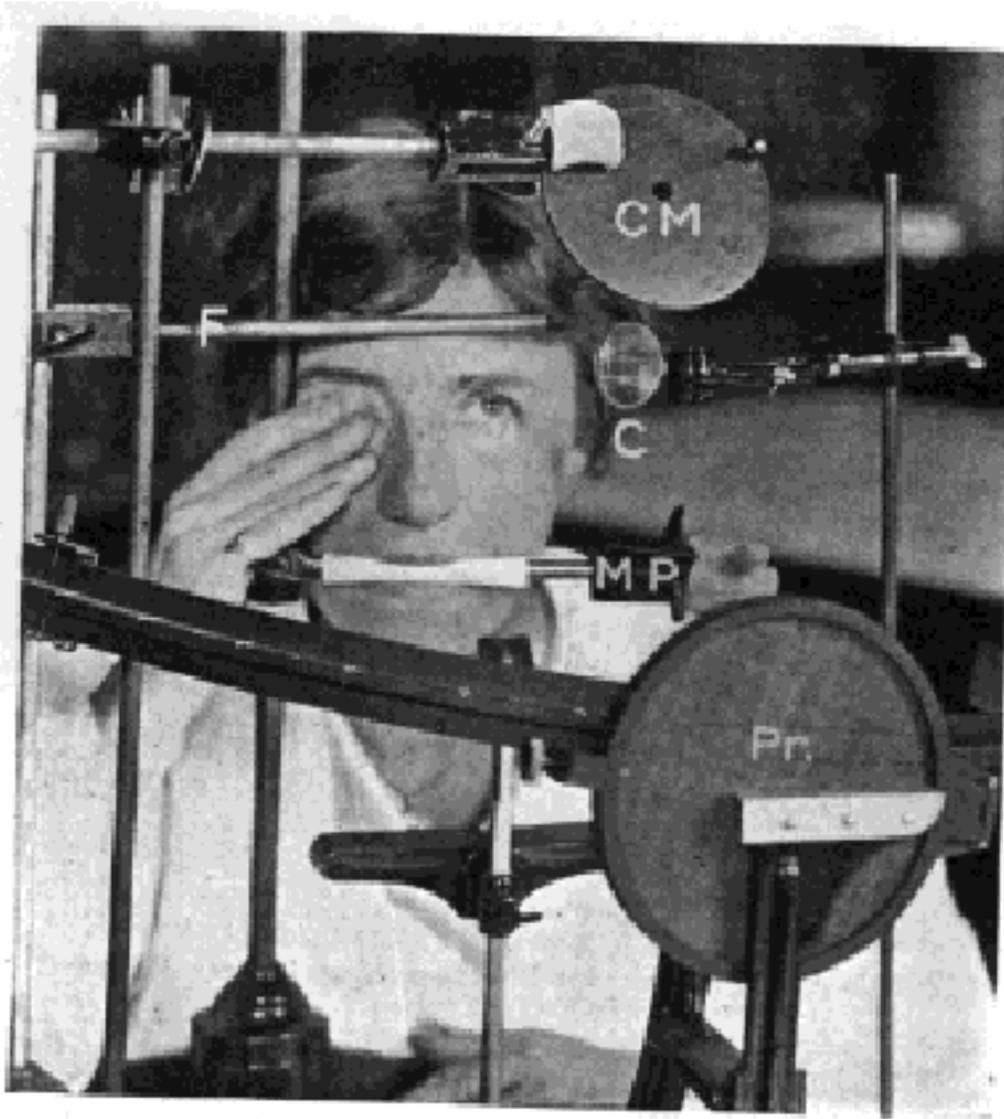

Fig. 25. Arrangements for Holding the Head of the Subject

Steady While Images Were Being Photographed

CM, concave mirror; F, forehead rest; C, condenser, MP mouthpiece; Pr, perimeter.

a clearer and more constant image, but it still was not sufficiently reliable to be measured. To Helmholtz the indistinct image of a naked flame seemed to show an appreciable change, while the images obtained by the aid of the diaphragm showed it more clearly; but I was

Inconstancy of Candle Image 57

unable, either with a diaphragm or without it, to obtain images which I considered sufficiently distinct to

be reliable.

Men who had been teaching and demonstrating Helmholtz's theory repeated his experiments for my benefit; but the images which they obtained on the front of the lens did not seem to me any better than my own. After

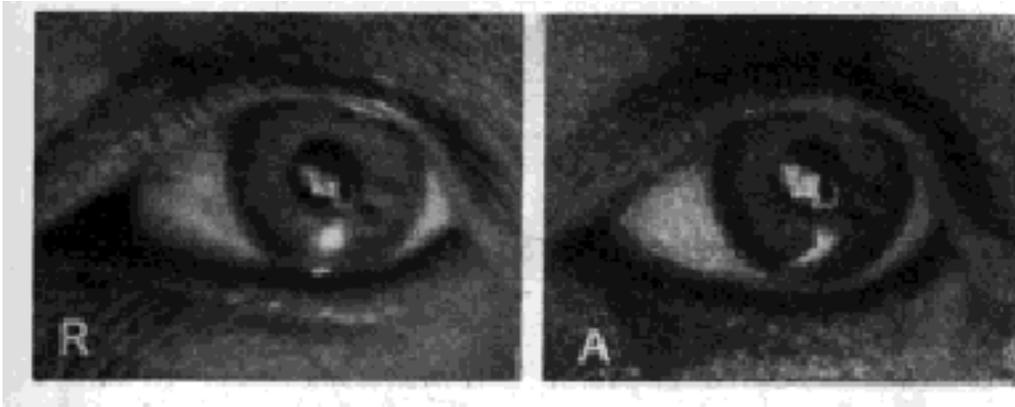

Fig. 26. Image of Electric Filament on the Front of the Lens

R, rest; A, accommodation. Under the magnifying glass no change can be observed in the size of the two images. The image at the right looks larger only because it is more distinct. To support the theory of Helmholtz it ought to be the smaller. The comet's tail at the left of the two images is an accidental reflection from the cornea. The spot of light beneath is a reflection from the light used to illuminate the eye while the photographs were being taken. It took two years to get these pictures.

studying these images almost daily for more than a year I was unable to make any reliable observation regarding the effect of accommodation upon them. In fact, it seemed that an infinite number of appearances might be obtained on the front of the lens when a candle was used as the source of illumination. At times the image became smaller during accommodation and seemed to sustain the theory of Helmholtz; but just as frequently it became larger. At other times it was impossible to tell what it did.

58 Accommodation: Study of Images

With a thirty-watt lamp, a fifty-watt lamp, a 250-watt lamp and a 1000-watt lamp, there was no improvement. The light of the sun reflected from the front of the lens produced an image just as cloudy and uncertain as the reflections from other sources of illumination, and just as variable in shape, intensity and size. To sum it all up, I was convinced that the anterior surface of the lens

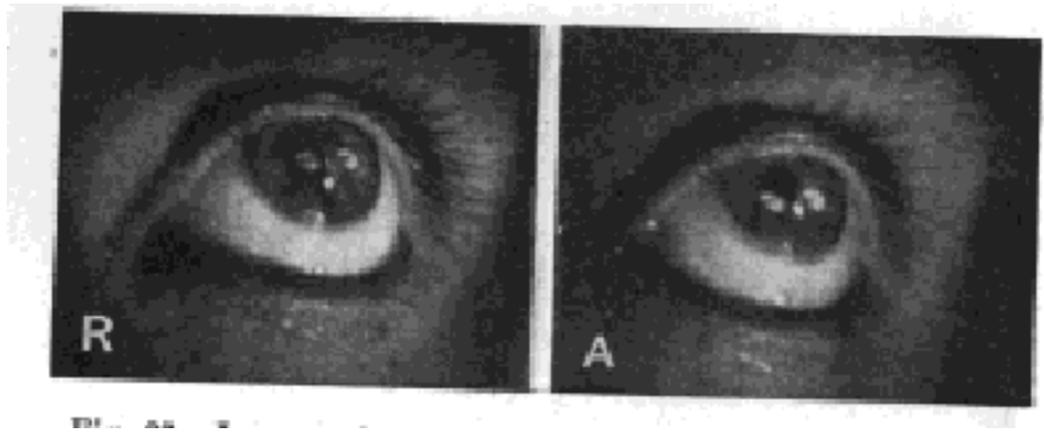

Fig. 27. Images of the Electric Filament Reflected Simultaneously From the Cornea and Lens

R, rest; A, accommodation. The size of the images in both pictures is the same. The corneal image is so small that it has not been noticeably altered by the slight change that takes place in the cornea during accommodation. In A both images have changed their position and the end of the reflection from the lens has been cut off by the iris, but its width remains the same. The white spot between the two images of the filament is a reflection from the lamp used to illuminate the eye. Note that in A more of the sclera is visible, owing to the elongation of the eyeball during accommodation.

was a very poor reflector of light, and that no reliable images could be obtained from it by the means described.

After a year or more of failure I began to work at an aquarium on the eyes of fish. It was a long story of failure. Finally I became able, with the aid of a strong light - 1000 watts - a diaphragm with a small opening and a condenser, to obtain, after some difficulty, a clear

Image on the Lens Photographed 59

and distinct image from the cornea of fish. This image was sufficiently distinct to be measured, and after many months a satisfactory photograph was obtained. Then the work was resumed on the eyes of human beings. The strong light, combined with the diaphragm and condenser, the use of which was suggested by their use to improve the illumination of a glass slide under the microscope, proved to be a decided improvement over the method of Helmholtz, and by means of this technique an image was at last obtained on the front of the lens which was sufficiently clear and distinct to be photographed. This was the first time, so far as published records show, that an image of any kind was ever photographed from the front of the lens. Professional photographers whom I consulted with a view to securing their assistance assured me that the thing could not be done, and declined to attempt it. I was therefore obliged to learn photography, of which I had previously known nothing, myself, and I then found that so far as

the image obtained by the method of Helmholtz is concerned the professionals were right.

The experiments were continued until, after almost four years of constant labor, I obtained satisfactory pictures before and after accommodation and during the production of myopia and hypermetropia, not only of images on the front of the lens, but of reflections from the iris, cornea, the front of the sclera (white of the eye) and the side of the sclera. I also became able to obtain images on any surface at will without reflections from the other parts. Before these results were obtained, however, many difficulties had still to be overcome.

Complicating reflections were a perpetual source of trouble. Reflections from surrounding objects were easily

60 Accommodation: Study of Images

prevented; but those from the sides of the globe of the electric light were difficult to deal with, and it was useless to try to obtain images on the front of the lens until they had been eliminated, or reduced to a minimum, by

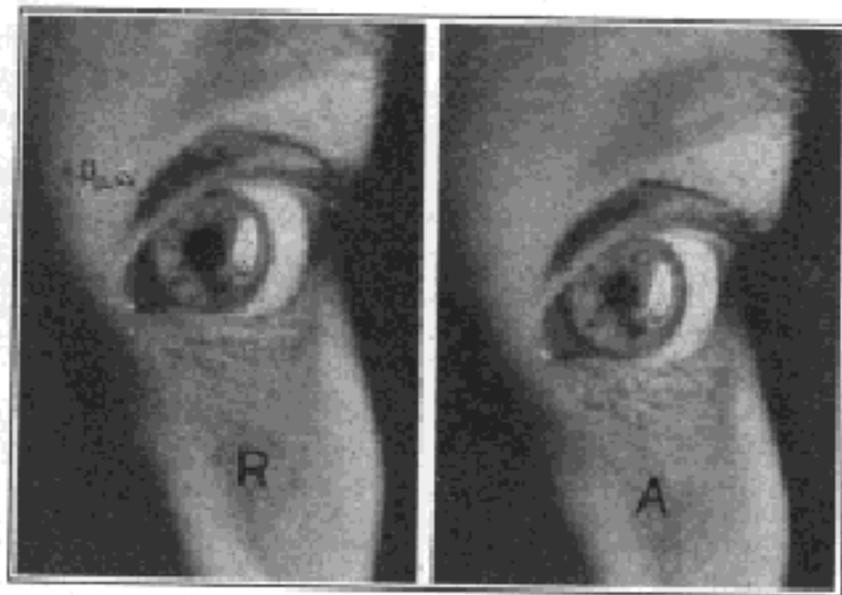

Fig. 28. Image of Electric Filament Upon the Cornea

R, rest; A, accommodation. The image is smaller in A, but the change is so slight as to be scarcely noticeable, showing that the alteration in the shape of the cornea during accommodation is very slight. For this reason the ophthalmometer, with its small image, has been thought to demonstrate that the cornea did not change during accommodation.

a proper adjustment of the light. The same apparent adjustment did not, however, always give similar results. Sometimes there would be no reflections for days; then would come a day when, with the light apparently at the same angle, they would reappear.

With some adjustments of the light multiple images were seen reflected from the front of the lens. Sometimes these images were arranged in a horizontal line, sometimes in a vertical one and sometimes at angles of

Unexplained Difficulties 61

different degrees, while their distance from each other also varied. Usually there were three of them; sometimes there were more; and sometimes there were only two. Occasionally they were all of the same size, but usually they varied, there being apparently no limit to their possibilities of change in this and other respects. Some of them were photographed, indicating that they were real reflections. Changes in the distance of the diaphragm from the light and from the condenser, and alterations in the size and shape of its opening, appeared to make no difference. Different adjustments of the condenser were equally without effect. Changes in the angle at which the light was adjusted sometimes lessened the number of images and sometimes increased them, until at last an angle was found at which but one image was seen. The images appear, in fact, to have been caused by reflections from the globe of the electric light.

Even after the light had been so adjusted as to eliminate reflections it was often difficult, or impossible, to get a clear and distinct image of the electric filament upon the front of the lens. One could rearrange the condenser and the diaphragm and change the axis of fixation, and still the image would be clouded or obscured and its outline distorted. The cause of the difficulty appeared to be that the light was not adjusted at the best angle for the purpose and it was not always possible to determine the exact axis at which a clear, distinct image would be produced. As in the case of the reflections from the sides of the globe, it seemed to vary without a known cause. This was true, however: that there were angles of the axis of the globe which gave better images than others, and that what these angles were could not be determined with exactness. I have

62 Accommodation: Study of Images

labored with the light for two or three hours without finding the right angle. At other times the axis would remain unchanged for days, giving always a clear, distinct image.

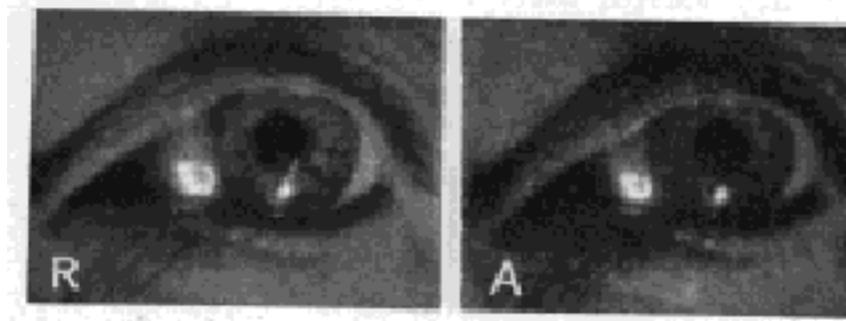

Fig. 29. Image of Electric Filament on the Front of the Sclera

R, rest; A, accommodation. During accommodation the front of the sclera becomes more convex, because the eyeball has elongated, just as a camera is elongated when it is focussed upon a near object. The spot of light on the cornea is an accidental reflection.

The results of these experiments confirmed the conclusions drawn from the previous ones, namely, that accommodation is due to a lengthening of the eyeball, and not to a change in the curvature of the lens. They also confirmed, in a striking manner, my earlier conclusions as to the conditions under which myopia and hypermetropia are produced.'

I The images photographed from the front of the lens

did not show any change in size or form during accommodation. The image on the back of the lens also remained unchanged, as observed through the telescope

of the ophthalmometer; but as there is no dispute about

its behavior during accommodation, it was not photo

graphed. Images photographed from the iris before

1 Bates: *The Cause of Myopia*, N. Y. Med. Jour., March 16, 1912.

No Change in Iris Image 68

and during accommodation were also the same in size and form, as was to be expected from the character of the lens images. If the lens changed during accommodation, the iris, which rests upon it, would change also.

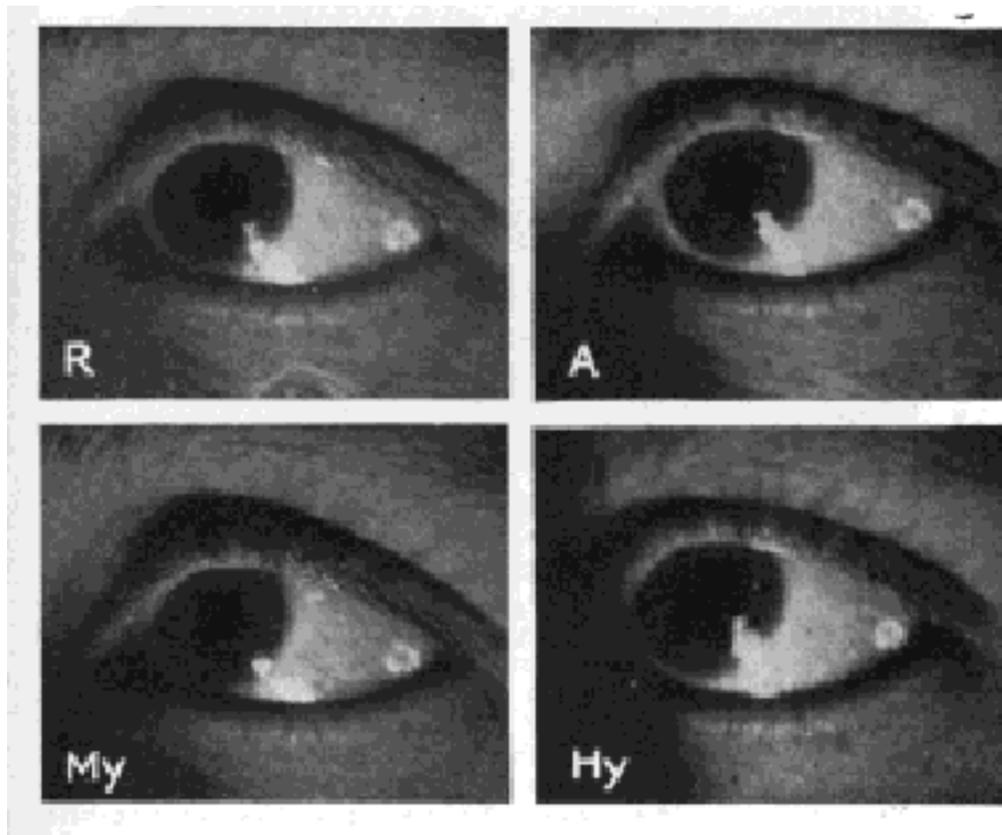

Fig. 30. Images on the Side of the Sclera

R, rest; A, accommodation. The image in A is the larger, indicating a flattening of the side of the sclera as the eyeball elongates. My, Myopia. The eye is straining to see at the distance and the image is larger, indicating that the eyeball has elongated, resulting in a flattening of the side of the sclera. Hy, Hypermetropia. The eye is straining to see at two inches. The image is the smallest of the series, indicating that the eyeball has become shorter than in any of the other pictures, and the side of the sclera more convex. The two lower pictures confirm the author's previous observations that farsight is produced when the eye strains to see near objects and nearsight when it strains to see distant objects.

64 Accommodation: Study of Images

The images photographed from the cornea and from the front and side of the sclera showed, however, a series

Fig. 31. Multiple Images Upon the Front of the Lens

This picture illustrates one of the difficulties that had to be overcome in photographing images reflected from various parts of the eyeball. Unless the light was adjusted at precisely the right angle the filament was multiplied by reflection from the sides of the globe. Usually the image was doubled, sometimes it was tripled, as shown in the picture, and sometimes it was quadrupled. Often days of labor were required to eliminate these reflections, and for reasons that were not definitely determined the same adjustment did not always give the same results. Sometimes all would go well for days, and then, without any apparent reason, the multiple images would return.

of four well-marked changes, according to whether the vision was normal or accompanied by a strain. During accommodation the images from the cornea were smaller than when the eye was at rest, indicating elongation of the eyeball and a consequent increase in the convexity of the cornea. But when an unsuccessful effort was made to see at the near-point, the image became larger, indicating that the cornea had become less convex, a condi

A Series of Four Changes 65

tion which one would expect when the optic axis was shortened, as in hypermetropia. When a strain was made to see at a distance the image was smaller than when the eye was at rest, again indicating elongation of the eyeball and increased convexity of the cornea.

The images photographed from the front of the sclera showed the same series of changes as the corneal images, but those obtained from the side of the sclera were found to have changed in exactly the opposite manner, being larger where the former were smaller and vice versa, a

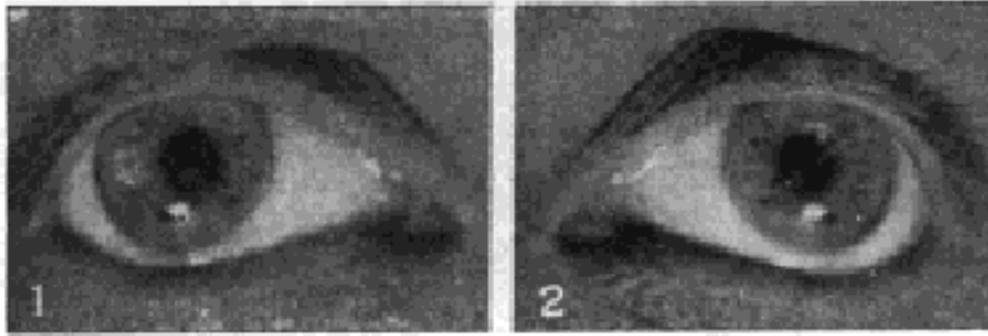

Fig. 32. Reflection of the Electric Filament From the Iris

This picture is shown to illustrate the fact that it is possible to get a reflection from any reflecting surface of the eyeball without reflections from the other parts, although these may be exposed. This is done by changing the angle of the light to the eye. In No. 1 observations of the eye at the time the picture was taken demonstrated that the image was from the iris, not from the cornea, and the fact is also apparent in the picture. (Compare the image with the corneal reflection in Fig. 28.) In No. 2, where the image overlaps the margin of the pupil, the fact that the reflection is from the iris is manifest from the circumstance that only part of the filament is seen. If it were from the cornea, the whole of it would be reflected. Note in this picture that there is no reflection from the lens. The images on the iris did not change their size or shape during accommodation, demonstrating again that the lens, upon which the iris rests, does not change its shape when the eye adjusts itself for near vision.

66 Accommodation: Study of Images

difference which one would naturally expect from the fact that when the front of the sclera becomes more convex the sides must become flatter.

When an effort was made to see at a distance the image reflected from the side of the sclera was larger than the image obtained when the eye was at rest, indicating that this part of the sclera had become less convex or flatter, because of elongation of the eyeball. The image obtained during normal accommodation was also larger than when the eye was at rest, indicating again a flattening of the side of the sclera. The image obtained, however, when an effort was made to see near was much smaller than any of the other images, indicating that the sclera had become more convex at the side, a condition which one would expect when the eyeball was shortened, as in hypermetropia.

The most pronounced of the changes were noted in the images reflected from the front of the sclera. Those on the side of the sclera were less marked, and, owing to the difficulty of photographing a white image on a white background, could not always be readily seen on the photographs. They were always plainly apparent, however, to the observer, and still more so to the subject, who regarded them in a concave mirror. The alterations in the size of the corneal image were so slight that they did not show at all in the photographs, except when the image was

large, a fact which explains why the ophthalmometer, with its small image, has been thought to show that the cornea did not change during accommodation. They were always apparent, however, to the subject and observer.

The corneal image was one of the easiest of the series to produce and the experiment is one which almost any

No Change in Back of Lens 67

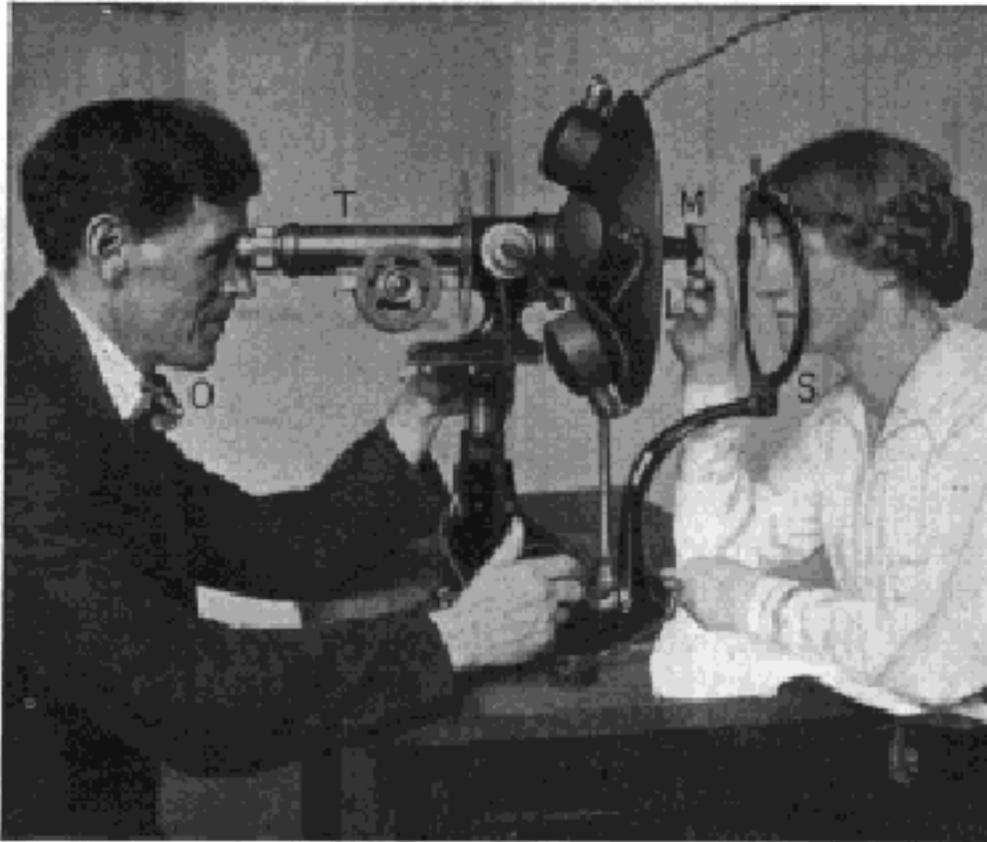

Fig. 33. Demonstrating That the Back of the Lens Does Not
Change During Accommodation.

The filament of an electric light (L) is shining into the eye of the subject (S), and the reflection on the back of the lens can be seen by the observer (O) in the telescope (T). The subject holds in her hand, at a distance of four inches, a mirror on which is pasted a small letter, and in which is reflected a Snellen test card hung above and behind her head at a distance of twenty feet. The retinoscope reveals that when she looks at the reflection of the test card and reads the bottom line the eye is at rest, and that when she looks at the letter pasted on the mirror it accommodates. The image on the lens does not change during these changes of focus. The telescope is the telescope of the ophthalmometer, the prisms having been removed. As there is no dispute about the behavior

of the back of the lens during accommodation this image was not photographed.

68 Accommodation Study of Images

The corneal image was one of the easiest of the series to produce and the experiment is one which almost anyone can repeat, the only apparatus required being a fifty-candlepower lamp - an ordinary electric globe - and a concave mirror fastened to a rod which moves back and forth in a groove so that the distance of the mirror from the eye can be altered at will. A plane mirror might also be used; but the concave glass is better, because it magnifies the image. The mirror should be so arranged that it reflects the image of the electric filament on the cornea, and so that the eye of the subject can see this reflection by looking straight ahead. The image in the mirror is used as the point of fixation, and the distance at which the eye focuses is altered by altering the distance of the mirror from the eye. The light can be placed within an inch or two of the eye, as the heat is not great enough to interfere with the experiment. The closer it is the larger the image, and according to whether it is adjusted vertically, horizontally, or at an angle, the clearness of the reflection may vary. A blue glass screen can be used, if desired, to lessen the discomfort of the light. If the left eye is used by the subject - and in all the experiments it was found to be the more convenient for the purpose - the source of light should be placed to the left of that eye and as much as possible to the front of it, at an angle of about forty-five degrees. For absolute accuracy the light and the head of the subject should be held immovable, but for demonstration this is not essential. Simply holding the bulb in his hand the subject can demonstrate that the image changes according to whether the eye is at rest, accommodating normally for near vision, or straining to see at a near or a distant point.

In the original report were described possible sources of error and the means taken to eliminate them.

CHAPTER VI

THE TRUTH ABOUT ACCOMMODATION AS DEMONSTRATED BY CLINICAL OBSERVATIONS

THE testimony of the experiments described in the preceding chapters to the effect that the lens is not a factor in accommodation is confirmed by numerous observations on the eyes of adults and children, with normal vision, errors of refraction, or amblyopia, and on the eyes of adults after the removal of the lens for cataract.

It has already been pointed out that the instillation of atropine into the eye is supposed to prevent accommodation by paralyzing the muscle credited with controlling the shape of the lens. That it has this effect is stated in every text-book on the subject,¹ and the drug is daily used in the fitting of glasses for the purpose of eliminating the supposed influence of the lens upon refractive states.

In about nine cases out of ten the conditions resulting from the instillation of atropine into the eye fit the theory upon which its use is based; but in the tenth case they do not, and every ophthalmologist of any experience has noted some of these tenth cases. Many of them are reported in the literature, and many of them have come under my own observation. According to the theory,

¹ Certain substances have the power of producing dilation of the pupil (mydriasis) and hence are termed mydriatics. At the same time they act upon the ciliary body diminishing and when applied in sufficient strength completely paralyzing the power of accommodation thus rendering the eye for some time unalterably focused for the farthest point - Herman Snellen Jr.: *Mydriatics and Myotics System of Diseases of the Eye*, edited by Norris and Oliver, 1897-1900, vol. ii, p. 30.

70 Accommodation: Clinical Observations

atropine ought to bring out latent hypermetropia in eyes either apparently normal, or manifestly hypermetropic, provided, of course, the patient is of the age during which

if the lens is supposed to retain its elasticity. The fact is that it sometimes produces myopia, or changes hypermetropia into myopia, and that it will produce both myopia and hypermetropia in persons over seventy years *L* Of age, when the lens is supposed to be as hard as a

- stone, as well as in cases in which the lens is hard with incipient cataract. Patients with eyes apparently normal will, after the use of atropine, develop hypermetropic astigmatism, or myopic

astigmatism, or compound myopic astigmatism, or mixed astigmatism.¹ In other cases the drug will not interfere with the accommodation, or alter the refraction in any way. Furthermore, when the vision has been lowered by atropine the subjects have often become able, simply by resting their eyes, to read diamond type at six inches. Yet atropine is supposed to rest the eyes by affording relief to an overworked muscle.

In the treatment of squint and amblyopia I have often Used atropine in the better eye for more than a year, in order to encourage the use of the amblyopic eye; and at the end of this time, while still under the influence of atropine, such eyes have become able in a few hours, or less, to read diamond type at six inches (see Chapter XXII). The following are examples of many similar cases that might be cited:

A boy of ten had hypermetropia in both eyes, that of

1 In simple hypermetropic astigmatism one principal meridian is normal and the other, at right angles to it, is flatter. In simple myopic astigmatism the contrary is the case.; one principle meridian is normal and the other, at right angles to it more convex. In mixed astigmatism one principal meridian is too flat the other too convex. In compound hypermetropic astigmatism both principal meridians are flatter than normal one more so than the other

In compound myopic astigmatism both are more convex than normal, one more so than the other.

Atropine Fails to Paralyze Accommodation 71

the left or better eye amounting to three diopters. When atropine was instilled into this eye the hypermetropia was increased to four and a half diopters, and the vision lowered to 20/200. With a convex glass of four and a half diopters the patient obtained normal vision for the distance, and with the addition of another convex glass of four diopters he was able to read diamond type at ten inches (best). The atropine was used for a year, the pupil being dilated continually to the maximum. Meantime the right eye was being treated by methods to be described later. Usually in such cases the eye which is not being specifically treated improves to some extent with the others, but in this case it did not. At the end of the year the vision of the right eye had become normal; but that of the left eye remained precisely what it was at the beginning, being still 20/200 without glasses for the distance, while reading without glasses was impossible and the degree of the hypermetropia had not changed. Still under the influence of the atropine and still with the pupil dilated to the maximum, this eye was now treated separately; and in half an hour its vision had become normal both for the distance and the nearpoint, diamond type being read at six inches, all without glasses. According to the accepted theories, the ciliary muscle of this eye must not only have been completely paralyzed at the time, but must have been in a state of complete paralysis for a year. Yet the eye not only overcame four and a half diopters of hypermetropia, but added six diopters of accommodation, making a total of ten and a half. It remains for those who adhere to the accepted

theories to say how such facts can be reconciled with them.

Equally, if not more remarkable, was the case of a

72 Accommodation: Clinical Observations

little girl of six who had two and a half diopters of hypermetropia in her right or better eye, and six in the other, with one diopter of astigmatism. With the better eye under the influence of atropine and the pupil dilated to the maximum, both eyes were treated together for more than a year, and at the end of that time, the right being still under the influence of the atropine, both became able to read diamond type at six inches, the right doing it better, if anything, than the left. Thus, in spite of the atropine, the right eye not only overcame two and a half diopters of hypermetropia, but added six diopters of accommodation, making a total of eight and a half. In order to eliminate all possibility of latent hypermetropia in the left eye - which in the beginning had six diopters - the atropine was now used in this eye and discontinued in the other, the eye education being continued as before. Under the influence of the drug there was a slight return of the hypermetropia; but the vision quickly became normal again, and although the atropine was used daily for more than a year, the pupil being continually dilated to the maximum, it remained so, diamond type being read at six inches without glasses during the whole period. It is difficult for me to conceive how the ciliary muscle could have had anything to do with the ability of this patient to accommodate after atropine had been used in each eye separately for a year or more at a time.

According to the current theory, atropine paralyzes the ciliary muscle and thus, by preventing a change of curvature in the lens, prevents accommodation. When accommodation occurs, therefore, after the prolonged use of atropine, it is evident that it must be due to some factor or factors other than the lens and the ciliary muscle. The evidence of such cases against the accepted

Aphakia and Presbyopia 73

theories is, in fact, overwhelming; and according to these theories the other factors cited in this chapter are equally inexplicable. All of these facts, however, are in entire accord with the results of my experiments on the eye muscles of animals and my observations regarding the behavior of images reflected from various parts of the eyeball. They strikingly confirm, too, the testimony of the experiments with atropine, which showed that the accommodation could not be paralyzed completely and permanently unless the atropine was injected deep into the orbit, so as to reach the oblique muscles, the real muscles of accommodation, while hypermetropia could not be prevented when the eyeball was stimulated with electricity without a similar use of atropine, resulting in the paralysis of the recti muscles.

As has already been noted, the fact that after the removal of the lens for cataract the eye often appears to accommodate just as well as it did before is well known. Many of these cases have come under my own observation. Such patients have not only read diamond type with only their distance glasses on, at thirteen and ten inches and at a less distance, but one man was able to read without any glass at all. In all these cases the retinoscope demonstrated that the apparent act of accommodation was real, being

accomplished, not by the "interpretation of circles of diffusion," or by any of the other methods by which this inconvenient phenomenon is commonly explained, but by an accurate adjustment of the focus to the distances concerned.

The cure of presbyopia (see Chapter XX) must also be added to the clinical testimony against the accepted theory of accommodation. On the theory that the lens is a factor in accommodation such cures would be mani

74 Accommodation: Clinical Observations

festly impossible. The fact that rest of the eyes improves the sight in presbyopia has been noted by others, and has been attributed to the supposed fact that the rested ciliary muscle is able for a brief period to influence the hardened lens; but while it is conceivable that this might happen in the early stages of the condition and for a few moments, it is not conceivable that permanent relief should be obtained by this means, or that lenses which are, as the saying goes, as "hard as a stone," should be influenced, even momentarily.

A truth is strengthened by an accumulation of facts. A working hypothesis is proved not to be a truth if a single fact is not in harmony with it. The accepted theories of accommodation and of the cause of errors of refraction require that a multitude of facts shall be explained away. During more than thirty years of clinical experience, I have not observed a single fact that was not in harmony with the belief that the lens and the ciliary muscle have nothing to do with accommodation and that the changes in the shape of the eyeball upon which errors of refraction depend are not permanent. My clinical observations have of themselves been sufficient to demonstrate this fact. They have also been sufficient to show how errors of refraction can be produced at will, and how they may be cured, temporarily in a few minutes, and permanently by continued treatment.

CHAPTER VII

THE VARIABILITY OF THE REFRACTION OF THE EYE

THE theory that errors of refraction are due to permanent deformations of the eyeball leads naturally to the conclusion, not only that errors of refraction are permanent states, but that normal refraction is also a continuous condition. As this theory is almost universally accepted as a fact, therefore, it is not surprising to find that the normal eye is generally regarded as a perfect machine which is always in good working order. No matter whether the object regarded is strange or familiar, whether the light is good or imperfect, whether the surroundings are pleasant or disagreeable, even under conditions of nerve strain or bodily disease, the normal eye is expected to have normal refraction and normal sight all the time. It is true that the facts do not harmonize with this view, but they are conveniently attributed to the perversity of the ciliary muscle, or if that explanation will not work, ignored altogether.

When we understand, however, how the shape of the eyeball is controlled by the external muscles, and how it responds instantaneously to their action, it is easy to see that no refractive state, whether it is normal or abnormal, can be permanent. This conclusion is confirmed by the retinoscope, and I had observed the facts long before the experiments described in the preceding chapters had offered a satisfactory explanation for it. During thirty years devoted to the study of refraction, I have found

75

76 Variability of the Refraction of the Eye

few people who could maintain perfect sight for more than a few minutes at a time, even under the most favorable conditions; and often I have seen the refraction change half a dozen times or more in a second, the variations ranging all the way from twenty diopters of myopia to normal. Similarly I have found no eyes with continuous or unchanging errors of refraction, all persons with errors of refraction having, at frequent intervals during the day and night, moments of normal vision, when their myopia, hypermetropia, or astigmatism, wholly disappears. The form of the error also changes, myopia even changing into hypermetropia, and one form of astigmatism into another.

Of twenty thousand school children examined in one year, more than half had normal eyes, with sight which was perfect at times; but not one of them had perfect sight in each eye at all times of the day. Their sight might be good in the morning and imperfect in the afternoon, or imperfect in the morning and perfect in the afternoon. Many children could read one Snellen test card: with perfect sight, while unable to see a different one perfectly. Many could also read some letters of the alphabet perfectly, while unable to distinguish other letters of the same size under similar conditions. The degree of this imperfect sight varied within wide limits, from one-third to one-tenth, or less. Its duration was also variable. Under some conditions it might continue for only a few minutes, or less; under others it might prevent the subject from seeing the blackboard for days, weeks, or even longer. Frequently all the pupils in a classroom were affected to this extent.

Among babies a similar condition was noted. Most

Changing Refraction of Infants 77

investigators have found babies hypermetropic. A few have found them myopic. My own observations indicate that the refraction of infants is continually changing. One child was examined under atropine on four successive days, beginning two hours after birth. A three per cent solution of atropine was instilled into both eyes, the pupil was dilated to the maximum, and other physiological symptoms of the use of atropine were noted. The first examination showed a condition of mixed astigmatism. On the second day there was compound hypermetropic astigmatism, and on the third compound myopic astigmatism. On the fourth one eye was normal and the other showed simple myopia. Similar variations were noted in many other cases.

What is true of children and infants is equally true of adults of all ages. Persons over seventy years of age have suffered losses of vision of variable degree and intensity, and in such cases the retinoscope always indicated an error of refraction. A man eighty years old, with normal eyes and ordinarily normal sight, had periods of imperfect sight which would last from a few minutes to half an hour or longer. Retinoscopy at such times always indicated myopia of four diopters or more.

During sleep the refractive condition of the eye is rarely, if ever, normal. Persons whose refraction is normal when they are awake will produce myopia, hypermetropia and astigmatism when they are asleep, or, if they have errors of refraction when they are awake, they will be increased during sleep. This is why people waken in the morning with eyes more tired than at any other time, or even with severe headaches. When the subject is under ether or chloroform, or unconscious from any other cause, errors of refraction are also produced or increased.

78 Variability of the Refraction of the Eye

When the eye regards an unfamiliar object an error of refraction is always produced. Hence the proverbial fatigue caused by viewing pictures, or other objects, in a museum. Children with normal eyes who can read perfectly small letters a quarter of an inch high at ten feet always have trouble in reading strange writing on the blackboard, although the letters may be two inches high. A strange map, or any map, has the same effect. I have never seen a child, or a teacher, who could look at a map at the distance without becoming nearsighted. German type has been accused of being responsible for much of the poor sight once supposed to be peculiarly a German malady; but if a German child attempts to read Roman print, it will at once become temporarily hypermetropic. German print, or Greek or Chinese characters, will have the same effect on a child, or other person, accustomed to Roman letters. Cohn repudiated the idea that German lettering was trying to the eyes.¹ On the contrary, he always found it "pleasant, after a

long reading of the monotonous Roman print, to return 'to our beloved German.'" Because the German characters were more familiar to him than any others he found them restful to his eyes. "Use," as he truly observed, "has much to do with the matter." Children learning to read, write, draw, or sew, always suffer from defective vision, because of the unfamiliarity of the lines or objects with which they are working.

A sudden exposure to strong light, or rapid or sudden changes of light, are likely to produce imperfect sight in the normal eye, continuing in some cases for weeks and months (see Chapter XVII).

1 Eyes and School-Books Pop. Sci. Monthly, May, 1881, translated from Deutsche Rundschau.

Causes of Defective Vision in Normal Eyes 79

Noise is also a frequent cause of defective vision in the normal eye. All persons see imperfectly when they hear an unexpected loud noise. Familiar sounds do not lower the vision, but unfamiliar ones always do. Country children from quiet schools may suffer from defective vision for a long time after moving to a noisy city. In school they cannot do well with their work, because their sight is impaired. It is, of course, a gross injustice for teachers and others to scold, punish, or humiliate such children.

Under conditions of mental or physical discomfort, such as pain, cough, fever, discomfort from heat or cold, depression, anger, or anxiety, errors of refraction are always produced in the normal eye, or increased in the eye in which they already exist.

The variability of the refraction of the eye is responsible for many otherwise unaccountable accidents. When people are struck down in the street by automobiles, or trolley cars, it is often due to the fact that they were suffering from temporary loss of sight. Collisions on railroads or at sea, disasters in military operations, aviation accidents, etc., often occur because some responsible person suffered temporary loss of sight.

To this cause must also be ascribed, in a large degree, the confusion which every student of the subject has noted in the statistics which have been collected regarding the occurrence of errors of refraction. So far as I am aware it has never been taken into account by any investigator of the subject; yet the result in any such investigation must be largely determined by the conditions under which it is made. It is possible to take the best eyes in the world and test them so that the subject will not be able to get into the Army. Again, the test

80 Variability of the Refraction of the Eye

may be so made that eyes which are apparently much below normal at the beginning, may in the few minutes required for the test, acquire normal vision and become able to read the test card perfectly.

CHAPTER VIII

WHAT GLASSES DO TO US

THE Florentines were doubtless mistaken in supposing that their fellow citizen (see page v) was the inventor of the lenses now so commonly worn to correct errors of refraction. There has been much discussion as to the origin of these devices, but they are generally believed to have been known at a period much earlier than that of Salvino degli Armati.: The Romans at least must have known something of the art of supplementing the powers of the eye, for Pliny tells us that Nero used to watch the games in the Colosseum through a concave gem set in a ring for that purpose. If, however, his contemporaries believed that Salvino of the Armati was the first to produce these aids to vision, they might well pray for the pardon of his sins; for while it is true that eyeglasses have brought to some people improved vision and relief from pain and discomfort, they have been to others simply an added torture, they always do more or less harm, and at their best they never improve the vision to normal.

That glasses cannot improve the sight to normal can be very simply demonstrated by looking at any color through a strong convex or concave glass. It will be noted that the color is always less intense than when seen with the naked eye; and since the perception of form depends upon the perception of color, it follows that both color and form must be less distinctly seen with glasses than without them. Even plane glass lowers the vision both for color and form, as everyone knows who has ever looked out of a window. Women who wear glasses for minor defects of vision often observe

82 What Glasses Do To Us

that they are made more or less color-blind by them, and in a shop one may note that they remove them when they want to match samples. If the sight is seriously defective, the color may be seen better with glasses than without them.

That glasses must injure the eye is evident from the facts given in the preceding chapter. One cannot see through them unless one produces the degree of refractive error which they are designed to correct. But refractive errors, in the eye which is left to itself, are never constant. If one secures good vision by the aid of concave, or convex, or astigmatic lenses, therefore, it means that one is maintaining constantly a degree of refractive error which otherwise would not be maintained constantly. It is only to be expected that this should make the condition worse, and it is a matter of common experience that it does. After people once begin to wear glasses their strength, in most cases, has to be steadily increased in order to maintain the degree of visual acuity secured by the aid of the first pair. Persons with presbyopia who put on glasses because they cannot read fine print too often find that after they have worn them for a time they cannot, without their aid, read the larger print that was perfectly plain to them before. A person with

myopia of 20/ 70 who puts on glasses giving him a vision of 20/20 may find that in a week's time his unaided vision has declined to 20/200, and we have the testimony of Dr. Sidler-Huguenin, of Zurich,¹ that of the thousands of myopes treated by him the majority grew steadily worse, in spite of all the skill he could apply to the fitting of glasses for them. When people break their glasses and go without them for a week or two, they

¹ Archiv. f. Augenh., vol. lxxix, 1915, translated in Arch. Opth., vol. xlv, No. 6, 1916.

The Eye Resents Glasses 83

frequently observe that their sight has improved. As a matter of fact the sight always improves, to a greater or less degree, when glasses are discarded, although the fact may not always be noted.

That the human eye resents glasses is a fact which no one would attempt to deny. Every oculist knows that patients have to "get used" to them, and that sometimes they never succeed in doing so. Patients with high degrees of myopia and hypermetropia have great difficulty in accustoming themselves to the full correction, and often are never able to do so. The strong concave glasses required by myopes of high degree make all objects seem much smaller than they really are, while convex glasses enlarge them. - These are unpleasantnesses that cannot be overcome. Patients with high degrees of astigmatism suffer some very disagreeable sensations when they first put on glasses, for which reason they are warned by one of the "Conservation of Vision" leaflets published by the Council on Health and Public Instruction of the American Medical Association to "get used to them at home before venturing where a misstep might cause a serious accident." ¹ Usually these difficulties are overcome, but often they are not, and it sometimes happens that those who get on fairly well with their glasses in the daytime never succeeded in getting used to them at night.

All glasses contract the field of vision to a greater or less degree. Even with very weak glasses patients are unable to see distinctly unless they look through the center of the lenses, with the frames at right angles to the line of vision; and not only is their vision lowered if they fail to do this, but annoying nervous symptoms,

¹ Lancaster: Wearing Glasses, p. 15.

84 What Glasses Do To Us

such as dizziness and headache, are sometimes produced. Therefore they are unable to turn their eyes freely in different directions. It is true that glasses are now ground in such a way that it is theoretically possible to look through them at any angle, but practically they seldom accomplish the desired result.

The difficulty of keeping the glass clear is one of the minor discomforts of glasses, but nevertheless a most annoying one. On damp and rainy days the atmosphere clouds them. On hot days the perspiration from the body may have a similar effect. On cold days they are often clouded by the moisture of the

breath. Every day they are so subject to contamination by dust and moisture and the touch of the fingers incident to unavoidable handling that it is seldom they afford an absolutely unobstructed view of the objects regarded.

Reflections of strong light from eyeglasses are often very annoying, and in the street may be very dangerous.

Soldiers, sailors, athletes, workmen and children have great difficulty with glasses because of the activity of their lives, which not only leads to the breaking of the lenses, but often throws them out of focus, particularly in the case of eyeglasses worn for astigmatism.

The fact that glasses are very disfiguring may seem a matter unworthy of consideration in a medical publication; but mental discomfort does not improve either the general health or the vision, and while we have gone so far toward making a virtue of what we conceive to be necessity that some of us have actually come to consider glasses becoming, huge round lenses in ugly tortoiseshell frames being positively fashionable at the present time, there are still some unperverted minds to which the wearing of glasses is mental torture and the sight of them upon others far from agreeable. Most human

Glasses to Relieve Strain 85

beings are, unfortunately, ugly enough without- putting glasses upon them, and to disfigure any of the really beautiful faces that we have with such contrivances is surely as bad as putting an import tax upon art. As for putting glasses upon a child it is enough to make the angels weep.

Up to a generation ago glasses were used only as an aid to defective sight, but they are now prescribed for large numbers of persons who can see as well or better without them. As explained in Chapter I, the hypermetropic eye is believed to be capable of correcting its own difficulties to some extent by altering the curvature of the lens, through the activity of the ciliary muscle. The eye with simple myopia is not credited with this capacity, because an increase in the convexity of the lens, which is supposed to be all that is accomplished by accommodative effort, would only increase the difficulty; but myopia is usually accompanied by astigmatism, and this, it is believed, can be overcome, in part, by alterations in the curvature of the lens. Thus we are led by the theory to the conclusion that an eye in which any error of refraction exists is practically never free, while open, from abnormal accommodative efforts. In other words, it is assumed that the supposed muscle of accommodation has to bear, not only the normal burden of changing the focus of the eye for vision at different distances, but the additional burden of compensating for refractive errors. Such adjustments, if they actually took place, would naturally impose a severe strain upon the nervous system, and it is to relieve this strain - which is believed to be the cause of a host of functional nervous troubles - quite as much as to improve the sight, that glasses are prescribed.

It has been demonstrated, however, that the lens is not

86 *What Glasses Do To Us*

a factor, either in the production of accommodation, or in the correction of errors of refraction. Therefore under no circumstances can there be a strain of the ciliary muscle to be relieved. It has also been demonstrated that when the vision is normal no error of refraction is present, and the extrinsic muscles of the eyeball are at rest. Therefore there can be no strain of the extrinsic muscles to be relieved in these cases. When a strain of these muscles does exist, glasses may correct its effects upon the refraction, but the strain itself they cannot relieve. On the contrary, as has been shown, they must make it worse. Nevertheless persons with normal vision who wear glasses for the relief of a supposed muscular strain are often benefited by them. This is a striking illustration of the effect of mental suggestion, and plane glass, if it could inspire the same faith, would produce the same result. In fact, many patients have told me that they had been relieved of various discomforts by glasses which I found to be simply plane glass. One of these patients was an optician who had fitted the glasses himself and was under no illusions whatever about them; yet he assured me that when he didn't wear them he got headaches.

Some patients are so responsive to mental suggestion that you can relieve their discomfort, or improve their sight, with almost any glasses you like to put on them. I have seen people with hypermetropia wearing myopic glasses with a great deal of comfort, and people with no astigmatism getting much satisfaction from glasses designed for the correction of this defect.

Landolt mentions the case of a patient who had for years worn prisms for insufficiency of the internal recti, and who found them absolutely indispensable for work, although the apices were toward the nose. The prescrip

Effects of Mental Suggestion 87

tion, which the patient was able to produce, called for prisms adjusted in the usual manner, with the apices toward the temples; but the optician had made a mistake which, owing to the patient's satisfaction with the result, had never been discovered. Landolt explained the case by "the slight effect of weak prisms and the great power of imagination"; and doubtless the benefit derived from the glasses was real, resulting from the patient's great faith in the specialist - described as "one of the most competent of ophthalmologists" - who prescribed them.

Some patients will even imagine that they see better with glasses that markedly lower the vision. A number of years ago a patient for whom I had prescribed glasses consulted an ophthalmologist whose reputation was much greater than my own, and who gave him another pair of glasses and spoke slightly of the ones that I had prescribed. The patient returned to me and told me how much better he could see with the second pair of glasses than he did with the first. I tested his vision with the new glasses, and found that while mine had given him a vision of 20/20 those of my colleague enabled him to see only 20/40. The simple fact was that he had been hypnotized by a great reputation into thinking he could see better when he actually saw worse; and it was hard to convince him that he was wrong, although he had to admit that when he looked at the test card he could see only half as much with the

new glasses as with the old ones.

When glasses do not relieve headaches and other nervous symptoms it is assumed to be because they were not properly fitted, and some practitioners and their patients exhibit an astounding degree of patience and

1 Anomalies of the Motor Apparatus of the Eye, System of Diseases of the Eye, vol. iv, pp. 154-155.

88 What Glasses Do To Us

perseverance in their joint attempts to arrive at the proper prescription. A patient who suffered from severe pains at the base of his brain was fitted sixty times by one specialist alone, and had besides visited many other eye and nerve specialists in this country and in Europe. He was relieved of the pain in five minutes by the methods presented in this book, while his vision, at the same time, became temporarily normal.

It is fortunate that many people for whom glasses have been prescribed refuse to wear them, thus escaping not only much discomfort but much injury to their eyes. Others, having less independence of mind, or a larger share of the martyr's spirit, or having been more badly frightened by the oculists, submit to an amount of unnecessary torture which is scarcely conceivable. One such patient wore glasses for twenty-five years, although they did not prevent her from suffering continual misery and lowered her vision to such an extent that she had to look over the tops when she wanted to see anything at a distance. Her oculist assured her that she might expect the most serious consequences if she did not wear the glasses, and was very severe about her practice of looking over instead of through them.

As refractive abnormalities are continually changing, not only from day to day and from hour to hour, but from minute to minute, even under the influence of atropine, the accurate fitting of glasses is, of course; impossible. In some cases these fluctuations are so extreme, or the patient so unresponsive to mental suggestion, that no relief whatever is obtained from correcting lenses, which necessarily become under such circumstances an added discomfort. At their best it cannot be maintained that glasses are anything more than a very unsatisfactory substitute for normal vision.

CHAPTER IX

THE CAUSE AND CURE OF ERRORS OF REFRACTION

IT has been demonstrated in thousands of cases that all abnormal action of the external muscles of the ; eyeball is accompanied by a strain or effort to see, and that with the relief of this strain the action of the muscles becomes normal and all errors of refraction disappear. The eye may be blind, it may be suffering from atrophy of the optic nerve, from cataract, or disease of the retina; but so long as it does not try to see, the external muscles act normally and there is no error of refraction. This fact furnishes us with the means by which all these conditions, so long held to be incurable, may be cured.

It has also been demonstrated that for every error of refraction there is a different kind of strain. The study of images reflected from various parts of the eyeball confirmed what had previously been observed, namely, that myopia (or a lessening of hypermetropia) is always associated with a strain to see at the distance, while hypermetropia (or/ a lessening of myopia) is always associated with a strain to see at the nearpoint; and the fact can be verified in a: few minutes by anyone who knows how to- use a retinoscope, provided only that the instrument is not brought nearer to the subject than six feet.

In an eye with previously normal vision a strain to see near objects always results in the temporary production of hypermetropia in one or all meridians. That is, the eye either becomes entirely hypermetropic, or some form

89

Hypermetropia

Patient reading fine print in a good light at thirteen inches, the object of vision being placed above the eye so as to be out of the line of the camera. Simultaneous retinoscopy indicated that the eye was focused at thirteen inches. The glass was used with the retinoscope to determine the amount of the refraction.

When the room was darkened the patient failed to read the fine print at thirteen inches and the retinoscope indicated that the eye was focused at a greater distance. When a conscious strain of considerable degree was made to see, the eye became hypermetropic.

The same boy trying to see a picture at twenty feet. The effort, manifested by staring, produces compound myopic astigmatism, as revealed by the retinoscope.

Emmetropia at the Near-Point 93

of astigmatism is produced of which hypermetropia forms a part. In the hypermetropic eye the hypermetropia is increased in one or all meridians. When the myopic eye strains to see a near object the myopia is lessened and emmetropia may be produced, the eye being focussed for parallel rays while still trying to see at the near-point. In some cases the emmetropia may even pass over into hypermetropia in one or all meridians. All these changes are accompanied by evidences of increasing strain, in the form of eccentric fixation

(see Chapter XI) and lower vision; but, strange to say, pain and fatigue are usually relieved to a marked degree. If, on the contrary, the eye with previously normal vision strains to see at the distance, temporary myopia is always produced in one or all meridians, and if the eye - is already myopic, the myopia is increased. If the hypermetropic eye strains to see a distant object, pain and fatigue may be produced or increased; but the hypermetropia and the eccen

The same boy making himself myopic voluntarily by partly closing the eyelids and making a conscious effort to read the test card at ten feet.

1 Emmetropia (from the Greek *emmetros*, in measure and *ops*, the eye) is that condition of the eye in which it is focussed for parallel rays This constitutes normal vision at the distance but is an error of refraction when it occurs at the near-point

94 Cause and Cure of Errors of Refraction

tric fixation are lessened-and the vision improves. This interesting result, it will be noted, is the exact contrary of what we get when the myope strains to see at the near-point. In some cases the hypermetropia is completely relieved, and emmetropia is produced, with a complete disappearance of all evidences of strain. This condition may then pass over into myopia, with an increase of strain as the myopia increases.

In other words the eye which strains to see at the nearpoint becomes flatter than it was before, in one or all meridians. If it was elongated to start with, it may pass

Fig. 37. Myopic Astigmatism Comes and Goes According as the
Subject Looks at Distant Objects With or Without Strain

No. 1. - Patient regarding the Snellen test card at ten feet without effort and reading the bottom line with normal vision.

No. 2. - The same patient making an effort to see a picture at twenty feet. The retinoscope indicated compound myopic astig

Strain in Lensless Eyes 95

from this condition through emmetropia, in which it is spherical, to hypermetropia, in which it is flattened; and if these changes take place unsymmetrically, astigmatism will be produced in connection with the other conditions. The eye which strains to see at the distance, on the contrary, becomes longer than it was before in one or all meridians, and may pass from the flattened condition of hypermetropia, through emmetropia, to the elongated condition of myopia. If these changes take place unsymmetrically, astigmatism will again be produced in connection with the other conditions.

What has been said of the normal eye applies equally to eyes from which the lens has been removed. This operation produces usually a condition of hypermetropia; but when there has previously been a condition of high myopia the removal of the lens may not be sufficient to correct it, and the eye may still remain myopic. In the first case a strain to see at the distance lessens the hypermetropia, and a strain to see at the near-point increases it; in the second a strain to see at the distance increases the myopia, and a strain to see at the nearpoint lessens it. For a longer or shorter period after the removal of the lens many

aphakic eyes strain to see at the near-point, producing so much hypermetropia that the patient cannot read ordinary print, and the power of accommodation appears to have been completely lost. Later, when the patient becomes accustomed to the situation, this strain is often relieved, and the eye becomes able to focus accurately upon near objects. Some rare cases have also been observed in which a measure of good vision both for distance and the nearpoint was obtained without glasses, the eyeball elongating sufficiently to compensate, to some degree, for the loss of the lens.

96 Cause and Cure of Errors of Refraction

Fig. 38. This Patient Had Had the Lens of the Right Eye Removed for Cataract and Was Wearing an Artificial Eye in the Left Socket. The Removal of the Lens Created a Condition of

Hypermetropia Which Was Corrected by a Convex Glass of Ten Diopters.

Should Have Been Impossible 97

NO. 1. - The patient is reading the Snellen test card at twenty feet with normal vision. NO. 2. - She is straining to see the test card at the same distance, and her hypermetropia is lessened by two diopters so that her glass now overcorrects it and she cannot see the card perfectly. NO. 3. - With a convex reading glass of thirteen diopters the right eye is focussed accurately at thirteen inches. NO. 4. - The patient is straining to see at the same distance and her hypermetropia is so increased that in order to read she would require a glass of fifteen diopters. On the basis of the accepted theory that the power of accommodation is wholly destroyed by the removal of the lens these changes in the refraction would have been impossible. The experiment was repeated several times and it was found that the error of refraction produced by straining to see varied, being sometimes more and sometimes less than two diopters.

98 Cause and Cure of Errors of Refraction

The phenomena associated with strain in the human eye have also been observed in the eyes of the lower animals. I have made many dogs myopic by inducing them to strain to see a distant object. One very nervous dog, with normal refraction, as demonstrated by the retinoscope, was allowed to smell a piece of meat. He became very much excited, pricked up his ears, arched his eyebrows and wagged his tail. The meat was then removed to a distance of twenty feet. The dog looked disappointed, but didn't lose interest. While he was watching the meat it was dropped into a box. A worried look came into his eyes. He strained to see what had become of it, and the retinoscope showed that he had become myopic. This experiment, it should be added, would succeed only with an animal possessing two active oblique muscles. Animals in which one of these muscles is absent or rudimentary are unable to elongate the eyeball under any circumstances.

Primarily the strain to see is a strain of the mind, and, as in all cases in which there is a strain of the mind, there is a loss of mental control. Anatomically the results of straining to see at a distance may be the same as those of regarding an object at the near point without strain; but in one case the eye does what the mind desires, and in the other it does not.

These facts appear sufficiently to explain why visual acuity declines as civilization advances. Under the conditions of civilized life men's minds are under a continual strain. They have more things to worry them than uncivilized man had, and they are not obliged to keep cool and collected in order that they may see and do other things upon which existence depends. If he allowed himself to get nervous, primitive man was Promptly

Relation of Civilization to Vision 99

eliminated; but civilized man survives and transmits his mental characteristics to posterity. The lower animals when subjected to civilized conditions respond to them in precisely the same way as do human creatures. I have examined many domestic and menagerie animals, and have found them, in many cases, myopic, although they neither read, nor write, nor sew, nor set type.

A decline in visual acuity at the distance, however, is

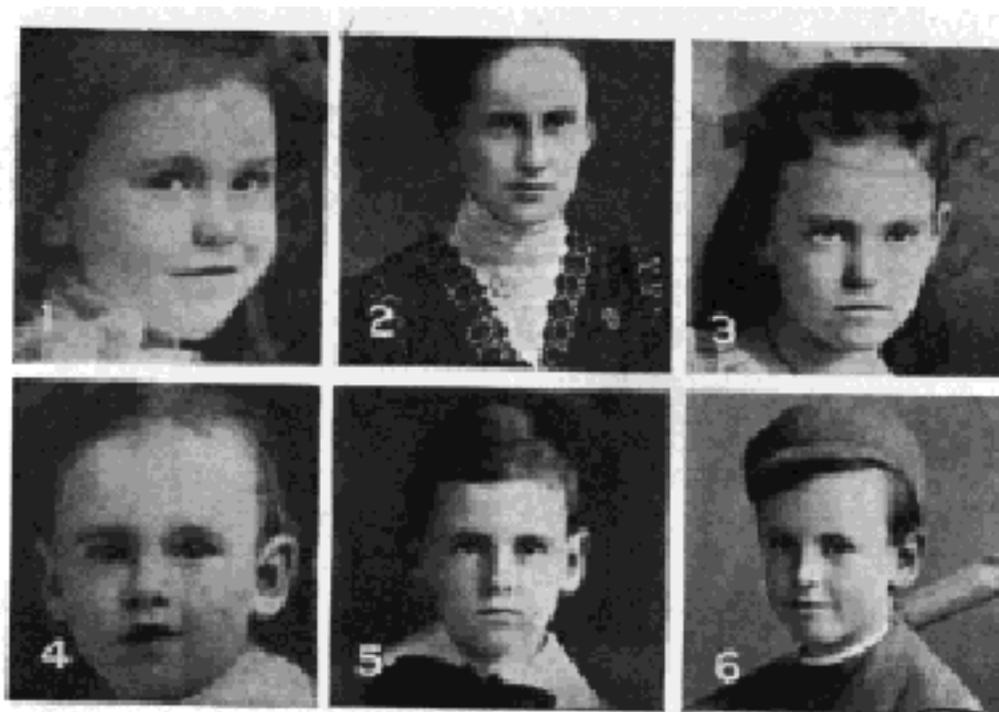

Fig. 39. A Family Group Strikingly Illustrating the Effect .

of the Mind Upon the Vision

No. 1. - Girl of four with normal eyes. No. 2. - The child's mother with myopia. No. 3. - The same girl at nine with myopia. Note that her expression has completely changed, and is now exactly like her mother's. Nos. 4, 5 and 6. - The girl's brother at two, six and eight. His eyes are normal in all three pictures. The girl has either inherited her mother's disposition to take things hard, or has been injuriously effected by her personality of strain. The boy has escaped both influences. In view of the prevailing theories about the relation of heredity to myopia, this picture is particularly interesting.

100 Cause and Cure of Errors of Refraction

no more a peculiarity of civilization than is a similar decline at the near-point. Myopes, although they see better at the near-point than they do at the distance, never see as well as does the eye with normal sight;

No. 4. - Pet dog with myopia which progressed from year to year.

Relaxation Cures 101

and in hypermetropia, which is more common than myopia, the sight is worse at the near-point than at the distance.

The remedy is not to avoid either near work or distant vision, but to get rid of the mental strain which underlies the imperfect functioning of the eye at both points; and it has: been demonstrated in thousands

of cases that this can always be done.

Fortunately, all persons are able to relax under certain conditions at will. In all uncomplicated errors of refraction the strain to see can be relieved, temporarily, by having the patient look at a blank wall without trying to see. -To secure permanent relaxation sometimes requires considerable time and much ingenuity. The same method cannot be used with everyone. The ways in which people strain to see are infinite, and the methods used to relieve the strain must be almost equally varied. Whatever the method that brings most relief, however, the end is always the same, namely relaxation. By constant repetition and frequent demonstration and by all means possible, the fact must be impressed upon the patient that perfect sight can be obtained only by relaxation. Nothing else matters.

Most people, when told that rest, or relaxation, will cure their eye troubles, ask why sleep does not do so. The answer to this question was given in Chapter VII. The eyes are rarely, if ever, completely relaxed in sleep, and if they are under a strain when the subject is awake, that strain will certainly be continued during sleep, to a greater or less degree, just as a strain of other parts of the body is continued.

The idea that it rests the eyes not to use them is also erroneous. The eyes were made to see with, and if when

102 Cause and Cure of Errors of Refraction

—

they are open they do not see, it is because they are under such a strain and have such a great error of refraction that they cannot see. Near vision, although accomplished by a muscular act, is no more a strain on them than is distant vision, although accomplished without the intervention of the muscles. The use of the muscles does not necessarily produce fatigue. Some men can run for hours without becoming tired. Many birds support themselves upon one foot during sleep, the toes tightly clasping the swaying bough and the muscles remaining unfatigued by the apparent strain. Fabre tells of an insect which hung back downward for ten months from the roof of its wire cage, and in that position performed all the functions of life, even to mating and laying its eggs. Those who fear the effect of civilization, with its numerous demands for near vision, upon the eye may take courage from the example of this marvelous little animal which, in a state of nature, hangs by its feet only at intervals, but in captivity can do it for ten months on end, the whole of its life's span, apparently without inconvenience or fatigue.¹

The fact is that when the mind is at rest nothing can tire the eyes, and when the mind is under a strain nothing can rest them. Anything that rests the mind will benefit the eyes. Almost everyone has observed that the eyes tire less quickly when reading an interesting book than when perusing something tiresome or difficult to comprehend. A schoolboy can sit up all night reading a novel without even thinking of his eyes, but if he tried to sit up all night studying his lessons he would soon find them getting very tired. A child whose vision was

1 The Wonders of Instinct English translation by de Mattos and Miall, 1918, pp. 36-38.

Time Required for a Cure 103

ordinarily so acute that she could see the moons of Jupiter with the naked eye became myopic when asked to do a sum in mental arithmetic, mathematics being a subject which was extremely distasteful to her. Sometimes the conditions which produce mental relaxation are very curious. One patient, for instance, was able to correct her error of refraction when she looked at the test card with her body bent over at an angle of about forty-five degrees, and the relaxation continued after she had assumed the upright position. Although the position was an unfavorable one, she had somehow got the idea that it improved her sight, and therefore it did so.

The time required to effect a permanent cure varies greatly with different individuals. In some cases five, ten, or fifteen minutes is sufficient, and I believe the time is coming when it will be possible to cure everyone quickly. It is only a question of accumulating more facts, and presenting these facts in such a way that the patient can grasp them quickly. At present, however, it is often necessary to continue the treatment for weeks and months, although the error of refraction may be no greater nor of longer duration than in those cases that are cured quickly. In most cases, too, the treatment must be continued for a few minutes every day to prevent relapse. Because a familiar object tends to relax the strain to see, the daily reading of the Snellen test card is usually sufficient for this purpose. It is also useful, particularly when the vision at the near-point is imperfect, to read fine print every day as close to the eyes as it can be done. When a cure is complete it is always permanent; but complete cures, which mean the attainment, not of what is ordinarily called normal sight, but of a measure of telescopic and microscopic vision,

104 Cause and Cure of Errors of Refraction

are very rare. Even in these cases, too, the treatment can be continued with benefit; for it is impossible to place limits to the visual powers of man, and no matter how good the sight, it is always possible to improve it. Daily practice of the art of vision is also necessary to

Fig. 41. - One of Many Thousands of Patients Cured of Errors
of Refraction by the Methods Presented in This Book

No. 1. - Man of thirty-six, 1902, wearing glasses for myopia. Note the appearance of effort in his eyes. He was relieved in 1904 by means of exercises in distant vision and obtained normal sight without glasses.

No. 2. - The same man five years later. No relapse.

prevent those visual lapses to which every eye is liable, no matter how good its sight may ordinarily be. It is true that no system of training will provide an absolute safeguard against such lapses in all circumstances; but the daily reading of small distant, familiar letters will do much to lessen the tendency to strain when disturbing circumstances arise, and all persons upon whose eyesight the safety of others depends should be required to do this.

Generally persons who have never worn glasses are

Cure at All Ages 103

more easily cured than those who have, and glasses should be discarded at the beginning of the treatment. When this cannot be done without too great discomfort, or when the patient has to continue his work during the treatment and cannot do so without glasses, their use must be permitted for a time; but this always delays the cure. Persons of all ages have been benefited by this treatment of errors of refraction by relaxation; but children usually, though not invariably, respond much more quickly than adults. If they are under twelve years of age, or even under sixteen, and have never worn glasses, they are usually cured in a few days, weeks, or months, and always within a year, simply by reading the Snellen test card every day.

CHAPTER X

STRAIN

TEMPORARY conditions may contribute to the strain to see which results in the production of errors of refraction; but its foundation lies in wrong habits of thought. In attempting to relieve it the physician has continually to struggle against the idea that to do anything well requires effort. This idea is drilled into us from our cradles. The whole educational system is based upon it; and in spite of the wonderful results attained by Montessori through the total elimination of every species of compulsion in the educational process, educators who call themselves modern still cling to the club, under various disguises, as *a* necessary auxiliary to the process of imparting knowledge.

It is as natural for the eye to see as it is for the mind to acquire knowledge, and any effort in either case is not only useless, but defeats the end in view. You may force a few facts into a child's mind by various kinds of compulsion, but you cannot make it learn anything. The facts remain, if they remain at all, as dead lumber in the brain. They contribute nothing to the vital processes of thought; and because they were not acquired naturally and not assimilated, they destroy the natural impulse of the mind toward the acquisition of knowledge, and by the time the child leaves school or college, as the case may be, it not only knows nothing but is, in the majority of cases, no longer capable of learning.

In the same way you may temporarily improve the sight by effort, but you cannot improve it to normal, and

106

When the Eye Tries to See 107

if the effort is allowed to become continuous, the sight will steadily deteriorate and may eventually be destroyed. Very seldom is the impairment or destruction of vision due to any fault in the construction of the eye. Of two equally good pairs of eyes one will retain perfect sight to the end of life, and the other will lose it in the kindergarten, simply because one looks at things without effort and the other does not.

The eye with normal sight never tries to see. If for any reason, such as the dimness of the light, or the distance of the object, it cannot see a particular point, it shifts to another. It never tries to bring out the point by staring at it, as the eye with imperfect sight is constantly doing.

Whenever the eye tries to see, it at once ceases to have normal vision. A person may look at the stars with normal vision; but if he tries to count the stars in any particular constellation, he will probably become myopic, because the attempt to do these things usually results in an effort to see. A patient was able to look at the letter K on the Snellen test card with normal vision, but when asked to count its twentyseven corners he lost it completely.

It obviously requires a strain to fail to see at the distance, because the eye at rest is adjusted for distant vision. If one does anything when one wants to see at the distance, one must do the wrong thing. The shape of the eyeball cannot be altered during distant vision without strain. It is equally a strain to fail to see at the near-point, because when the muscles respond to the mind's desire they do it without strain. Only by an effort can one prevent the eye from elongating at the near-point.

108 Strain

The eye possesses perfect vision only when it is absolutely at rest. Any movement, either in the organ or the object of vision, produces an error of refraction. With the retinoscope it can be demonstrated that even the necessary movements of the eyeball produce a slight error of refraction, and the moving pictures have given us a practical demonstration of the fact that it is impossible to see a moving object perfectly. When the movement of the object of vision is sufficiently slow, the resulting impairment of vision is so slight as to be inappreciable, just as the errors of refraction produced by slight movements of the eyeball are inappreciable; but when objects move very rapidly they can be seen only as a blur. For this reason it has been found necessary to arrange the machinery for exhibiting moving pictures in such a way that each picture is halted for a twenty-fourth of a second, and screened while it is moving into place. Moving pictures, accordingly, are never seen in motion.

The act of seeing is passive. Things are seen, just as they are felt, or heard, or tasted, without effort or volition on the part of the subject. When sight is perfect the letters on the test card are waiting, perfectly black and perfectly distinct, to be recognized. They do not have to be sought; they are there. In imperfect sight they are sought and chased. The eye goes after them. An effort is made to see them.

The muscles of the body are supposed never to be at rest. The blood-vessels, with their muscular coats, are never at rest. Even in sleep thought does not cease. But the normal condition of the nerves of sense - of hearing, sight, taste, smell and touch - is one of rest. They can be acted upon; they cannot act. The optic nerve, the

Mental Strain Reflected in the Eye 109

retina and the visual centers of the brain are as passive as the finger-nail. They have nothing whatever in their structure that makes it possible for them to do anything, and when they are the subject of effort from outside sources their efficiency is always impaired.

The mind is the source of all such efforts from outside sources brought to bear upon the eye. Every thought of effort in the mind, of whatever sort, transmits a motor impulse to the eye; and every such impulse causes a deviation from the normal in the shape of the eyeball and lessens the sensitiveness of

the center of sight. If one wants to have perfect sight, therefore, one must have no thought of effort in the mind. Mental strain of any kind always produces a conscious or unconscious eyestrain and if the strain takes the form of an effort to see, an error of refraction is always produced. A schoolboy was able to read the bottom line of the Snellen test card at ten feet, but when the teacher told him to mind what he was about he could not see the big C. Many children can see perfectly so long as their mothers are around; but if the mother goes out of the room, they may at once become myopic, because of the strain produced by fear. Unfamiliar objects produce eyestrain and a consequent error of refraction, because they first produce mental strain. A person may have good vision when he is telling the truth; but if he states what is not true, even with no intent to deceive, or if he imagines what is not true, an error of refraction will be produced, because it is impossible to state or imagine what is not true without an effort.

I may claim to have discovered that telling lies is bad

1 In this case and others to be mentioned later, the large letter at the top of the card read by the eye with normal vision at two hundred feet, was a "C."

110 Strain

for the eyes, and whatever bearing this circumstance may have upon the universality of defects of vision, the fact can easily be demonstrated. If a patient can read all the small letters on the bottom line of the test card, and either deliberately or carelessly miscalls any of them, the retinoscope will indicate an error of refraction. In numerous cases patients have been asked to state their ages incorrectly, or to try to imagine that they were a year older or a year younger than they actually were, and in every case when they did this the retinoscope indicated an error of refraction. A patient twenty-five years old had no error of refraction when he looked at a blank wall without trying to see; but if he said he was twenty-six, or if someone else said he was twenty-six, or if he tried to imagine that he was twenty-six, he became myopic. The same thing happened when he stated or tried to imagine that he was twenty-four. When he stated or remembered the truth his vision was normal, but when he stated or imagined an error he had an error of refraction.

Two little girl patients arrived one after the other one day, and the first accused the second of having stopped at Huyler's for an ice-cream soda, which she had been instructed not to do, being somewhat too much addicted to sweets. The second denied the charge, and the first, who had used the retinoscope and knew what it did to people who told lies, said:

"Do take the retinoscope and find out."

I followed the suggestion, and having thrown the light into the second child's eyes, I asked:

"Did you go to Huyler's?"

"Yes," was the response, and the retinoscope indicated no error of refraction.

Different Kinds of Strain 111

"Did you have an ice-cream soda?"

"No," said the child; but the telltale shadow moved in a direction opposite to that of the mirror, showing that she had become myopic and was not telling the truth.

The child blushed when I told her this and acknowledged that the retinoscope was right; for she had heard of the ways of the uncanny instrument before and did not know what else it might do to her if she said any thing more that was not true.

So sensitive is this test that if the subject, whether his vision is ordinarily normal or not, pronounces the initials of his name correctly while looking at a blank surface without trying to see, there will be no error of refraction; but if he miscalls one initial, even without any consciousness of effort, and with full knowledge that he is deceiving no one, myopia will be produced.

Mental strain may produce many different kinds of eyestrain. According to the statement of most authorities there is only one kind of eyestrain, an indefinite thing resulting from so-called overuse of the eyes, or an effort to overcome a wrong shape of the eyeball. It can be demonstrated, however, that there is not only a different strain for each different error of refraction, but a different strain for most abnormal conditions of the eye. The strain that produces an error of refraction is not the same as the strain that produces a squint, or a cataract,¹ or glaucoma,² or amblyopia,³ or inflammation of the conjunctiva⁴ or of the margin of the lids, or disease of the optic nerve or retina. All these conditions may exist

1 An opacity of the lens

2 A condition in which the eyeball becomes abnormally hard

condition in which there is a decline of vision without apparent cause

membrane covering the inner surface of the eyelid and the visible

part of the white of the eye.

112 *Strain*

with only a slight error of refraction, and while the relief of one strain usually means the relief of any others that may coexist with it, it sometimes happens that the strain associated with such conditions as cataract and glaucoma is relieved without the complete relief of the strain that causes the error of

refraction. Even the pain that so often accompanies errors of refraction is never caused by the same strain that causes these errors. Some myopes cannot read without pain or discomfort, but most of them suffer no inconvenience. When the hypermetrope regards an object at the distance the hypermetropia is lessened, but pain and discomfort may be increased. While there are many strains, however, there is only one cure for all of them. namely, relaxation.

The health of the eye depends upon the blood, and, circulation is very largely influenced by thought. When thought is normal - that is, not attended by any excitement or strain - the circulation in the brain is normal, the supply of blood to the optic nerve and the visual centers is normal, and the vision is perfect. When thought is abnormal the circulation is disturbed, the supply of blood to the optic nerve and visual centers is altered, and the vision lowered. We can consciously think thoughts which disturb the circulation and lower the visual power; we can also consciously think thoughts that will restore normal circulation, and thereby cure, not only all errors of refraction, but many other abnormal conditions of the eyes. We cannot by any amount of effort make ourselves see, but by learning to control our thoughts we can accomplish that end indirectly.

You can teach people how to produce any error of refraction, how to produce a squint, how to see two images of an object, one above another, or side by side,

As Quick as a Thought 113

or at any desired angle from one another, simply by teaching them how to think in a particular way. When the disturbing thought is replaced by one that relaxes, the squint disappears, the double vision and the errors of refraction are corrected; and this is as true of abnormalities of long standing as of those produced voluntarily. No matter what their degree or their duration their cure is accomplished just as soon as the patient | is able to secure mental control. The cause of any error of refraction, of a squint, or of any other functional disturbance of the eye, is simply a thought - a wrong thought - and the cure is as quick as the thought that relaxes. In a fraction of a second the highest degrees of refractive error may be corrected, a squint may disappear, or the blindness of amblyopia may be relieved. If the relaxation is only momentary, the correction is momentary. When it becomes permanent, the correction is permanent.

This relaxation cannot, however, be obtained by any sort of effort. It is fundamental that patients should understand this; for so long as they think, consciously or unconsciously, that relief from strain may be obtained by another strain their cure will be delayed.

CHAPTER XI

CENTRAL FIXATION

THE eye is a miniature camera, corresponding in many ways very exactly to the inanimate machine used in photography. In one respect, however, there is a great difference between the two instruments. The sensitive plate of the camera is equally sensitive in every part; but the retina has a point of maximum sensitiveness, and every other part is less sensitive in proportion as it is removed from that point. This point of maximum sensitiveness is called the "fovea centralis," literally the "central pit."

The retina, although it is an extremely delicate membrane, varying in thickness from one-eightieth of an inch to less than half that amount, is highly complex. It is composed of nine layers, only one of which is supposed to be capable of receiving visual impressions. This layer is composed of minute rodlike and conical bodies which vary in form and are distributed very differently in its different parts. In the center of the retina is a small circular elevation known, from the yellow color which it assumes in death and sometimes also in life, as the "macula lutea," literally the "yellow spot." In the center of this spot is the fovea, a deep depression of darker color. In the center of this depression there are no rods, and the cones are elongated and pressed very closely together. The other layers, on the contrary, become here extremely thin, or disappear altogether, so that the cones are covered with barely perceptible traces of them. Beyond the center of the fovea the cones become thicker and fewer

An Invariable Symptom. of Imperfect Sight 115

and are interspersed with rods, the number of which increases toward the margin of the retina. The precise function of these rods and cones is not clear; but it is a fact that the center of the fovea, where all elements except the cones and their associated cells practically disappear, is the seat of the most acute vision. As we withdraw from this spot, the acuteness of the visual perceptions rapidly decreases. The eye with normal vision, therefore, sees one part of everything it looks at best, and everything else worse, in proportion as it is removed from the point of maximum vision; and it is an invariable symptom of all abnormal conditions of the eyes, both functional and organic, that this central fixation is lost.

These conditions are due to the fact that when the sight is normal the sensitiveness of the fovea is normal, but when the sight is imperfect, from whatever cause, the sensitiveness of the fovea is lowered, so that the eye sees equally well, or even better, with other parts of the retina. Contrary to what is generally believed, the part seen best when the sight is normal is extremely small. The text-books say that at twenty feet an area having a diameter of half an inch can be seen with maximum vision, but anyone who tries at this distance to see every part of even the smallest letters of the Snellen test card - the diameter of which may be less than a quarter of an inch - equally well at one time will immediately become myopic. The

fact is that the nearer the point of maximum vision approaches a mathematical point, which has no area, the better the sight.

The cause of this loss of function in the center of sight is mental strain; and as all abnormal conditions of the eyes, organic as well as functional, are accompanied by

116 Central Fixation

mental strain, all such conditions must necessarily be accompanied by loss of central fixation. When the mind is under a strain the eye usually goes more or less blind. The center of sight goes blind first, partially or completely, according to the degree of the strain, and if the strain is great enough the whole or the greater part of the retina may be involved. When the vision of the center of sight has been suppressed, partially or completely, the patient can no longer see the point which he is looking at best, but sees objects not regarded directly as well, or better, because the sensitiveness of the retina has now become approximately equal in every part, or is even better in the outer part than in the center. Therefore in all cases of defective vision the patient is unable to see best where he is looking.

This condition is sometimes so extreme that the patient may look as far away from an object as it is possible to see it, and yet see it just as well as when looking directly at it. In one case it had gone so far that the patient could see only with the edge of the retina on the nasal side. In other words, she could not see her fingers in front of her face, but could see them if held at the outer side of her eye. She had only a slight error of refraction, showing that while every error of refraction is accompanied by eccentric fixation, the strain which causes the one condition is different from that which produces the other. The patient had been examined by specialists in this country and Europe, who attributed her blindness to disease of the optic nerve or brain; but the fact that vision was restored by relaxation demonstrated that the condition had been due simply to mental strain.

Eccentric fixation, even in its lesser degrees, is so unnatural that great discomfort, or even pain, can be produced in a few seconds by trying to see every part of an

When the Eye Possesses Central Fixation 117

area three or four inches in extent at twenty feet, or even less, or an area of an inch or less at the near-point, equally well at one time, while at the same time the retinoscope will demonstrate that an error of refraction has been produced. This strain, when it is habitual, leads to all sorts of abnormal conditions and is, in fact, at the bottom of most eye troubles, both functional and organic. The discomfort and pain may be absent, however, in the chronic condition, and it is an encouraging symptom when the patient begins to experience them.

When the eye possesses central fixation it not only possesses perfect sight, but it is perfectly at rest and can be used indefinitely without fatigue. It is open and quiet; no nervous movements are observable; and when it regards a point at the distance the visual axes are parallel. In other words, there are no muscular insufficiencies. This fact is not generally known. The textbooks state that muscular insufficiencies occur in eyes having normal sight, but I have never seen such a case. The muscles of the face and of the whole body are also at rest, and when the condition is habitual there are no wrinkles or dark circles around the eyes.

In most cases of eccentric fixation, on the contrary, the eye quickly tires, and its appearance, with that of the face, is expressive of effort or strain. The ophthalmoscope 1 reveals that the eyeball moves at irregular intervals, from side to side, vertically or in other directions. These movements are often so extensive as to be manifest by ordinary inspection, and are sometimes sufficiently marked to resemble nystagmus.² Nervous move

1 A shorter movement can be noted when the observer watches the optic nerve with the ophthalmoscope than when he views merely the exterior of the eye.

2 A condition in which there is a conspicuous and more or less rhythmic movement of the eyeball from side to side.

118 Central Fixation

ments of the eyelids may also be noted, either by ordinary inspection, or by lightly touching the lid of one eye while the other regards an object either at the near-point or the distance. The visual axes are never parallel, and the deviation from the normal may become so marked as to constitute the condition of squint. Redness of the conjunctiva and of the margins of the lids, wrinkles around the eyes, dark circles beneath them and tearing are other symptoms of eccentric fixation.

Eccentric fixation is a symptom of strain, and is relieved by any method that relieves strain; but in some cases the patient is cured just as soon as he is able to demonstrate the facts of central fixation. When he comes to realize, through actual demonstration of the fact, that he does not see best where he is looking, and that when he looks a sufficient distance away from a point he can see it worse than when he looks directly at it, he becomes able, in some way, to reduce the distance to which he has to look in order to see worse, until he can look directly at the top of a small letter and see the bottom worse, or look at the bottom and see the top worse. The smaller the letter regarded in this way, or the shorter the distance the patient has to look away from a letter in order to see the opposite part indistinctly, the greater the relaxation and the better the sight. When it becomes possible to look at the bottom of a letter and see the top worse, or to look at the top and see the bottom worse, it becomes possible to see the letter perfectly black and distinct. At first such vision may come only in flashes. The letter will come out distinctly for a moment and then disappear. But gradually, if the practice is continued, central fixation will become habitual.

Most patients can readily look at the bottom of the

The Use of Strong Lights 119

big C and see the top worse; but in some cases it is not only impossible for them to do this, but impossible for them to let go of the large letters at any distance at which they can be seen. In these extreme cases it sometimes requires considerable ingenuity, first to demonstrate to the patient that he does not see best where he is looking, and then to help him to see an object worse when he looks away from it than when he looks directly at it. The use of a strong light as one of the points of fixation, or of two lights five or ten feet apart, has been found helpful, the patient when he looks away from the light being able to see it less bright more readily than he can see a black letter worse when he looks away from it. It then becomes easier for him to see the letter worse when he looks away from it. This method was successful in the following case:

A patient with vision of 3/200, when she looked at a point a few feet away from the big C, said she saw the letter better than when she looked directly at it. Her attention was called to the fact that her eyes soon became tired and that her vision soon failed when she saw things in this way. Then she was directed to look at a bright object about three feet away from the card, and this attracted her attention to such an extent that she became able to see the large letter on the test card worse, after which she was able to look back at it and see it better. It was demonstrated to her that she could do one of two things: look away and see the letter better than she did before, or look away and see it worse. She then became able to see it worse all the time when she looked three feet away from it. Next she became able to shorten the distance successively to two feet, one foot, and six inches, with a constant improvement in vision; and finally she

120 Central Fixation

became able to look at the bottom of the letter and see the top worse, or look at the top and see the bottom worse. With practice she became able to look at the smaller letters in the same way, and finally she became able to read the ten line at twenty feet. By the same method also she became able to read diamond type, first at twelve inches and then at three inches. By these simple measures alone she became able, in short, to see best where she was looking, and her cure was complete.

The highest degrees of eccentric fixation occur in the high degrees of myopia, and in these cases, since the sight is best at the near-point, the patient is benefited by practicing seeing worse at this point. The distance can then be gradually extended until it becomes possible to do the same thing at twenty feet. One patient with a high degree of myopia said that the farther she looked away from an electric light the better she saw it, but by alternately looking at the light at the near-point and looking away from it she became able, in a short time, to see it brighter when she looked directly at it than when she looked away from it. Later she became able to do the same thing at twenty feet, and then she experienced a wonderful feeling of relief. No words, she said, could adequately describe it. Every nerve seemed to be relaxed, and a feeling of comfort and rest permeated her whole body. Afterward her progress was rapid. She soon

became able to look at one part of the smallest letters on the card and see the rest worse, and then she became able to read the letters at twenty feet.

On the principle that a burnt child dreads the fire, some patients are benefited by consciously making their sight worse. When they learn, by actual demonstration of the facts, just how their visual defects are produced.

Possibilities Cannot Be Limited 121

they unconsciously avoid the unconscious strain which causes them. When the degree of eccentric fixation is not too extreme to be increased;, therefore, it is a benefit to patients to teach them how to increase it. When a patient has consciously lowered his vision and produced discomfort and even pain by trying to see the big C, or a whole line of letters, equally well at one time, he becomes better able to correct the unconscious effort of the eye to see all parts of a smaller area equally well at one time. ,.

In learning to see best where he is looking it is usually- l best for the patient to think of the point not directly regarded as being seen less distinctly than the point he is | looking at, instead of thinking of the point fixed as being 1 seen best, as the latter practice has a tendency, in most 11 cases, to intensify the strain under which the eye is al- | ready laboring. One part of an object is seen best only **R** when the mind is content to see the greater part of it j indistinctly? and as the degree of relaxation increases the area of the part seen worse increases, until that seen best

becomes merely a point.

The limits of vision depend upon the degree of central fixation. A person may be able to read a sign half a mile away when he sees the letters all alike, but when taught to see one letter best he will be able to read smaller letters that he didn't know were there. The remarkable vision of savages, who can see with the naked eye objects for which most civilized persons require a telescope, is a matter of central fixation. Some people can see the moons of Jupiter, with the naked eye. It is not because of any superiority in the structure of their eyes, but because they have attained a higher degree of central fixation than most civilized persons do

122 Central Fixation

Not only do all errors of refraction and all functional disturbances of the eye disappear when it sees by central fixation, but many organic conditions are relieved or cured. I am unable to set any limits to its possibilities. I would not have ventured to predict that glaucoma, incipient cataract and syphilitic iritis could be cured by central fixation; but It is a fact that these conditions have disappeared when central}fixation was attained. Relief was often obtained in a few minutes, and, in rare cases, this relief was permanent. Usually, however, a permanent cure required more prolonged treatment. Inflammatory

conditions of all kinds, including inflammation of the cornea, iris, conjunctiva, the various coats of the eyeball and even the optic nerve itself, have been benefited by central fixation after other methods had failed. Infections, as well as diseases caused by protein poisoning and the poisons of typhoid fever, influenza, syphilis and gonorrhea, have also been benefited by it. Even with a foreign body in the eye there is no redness and no pain so long as central fixation is retained.

Since central fixation is impossible without mental control, central fixation of the eye means central fixation of the mind. It means, therefore, health in all parts of the body, for all the operations of the physical mechanism depend upon the mind. Not only the sight, but all the other senses - touch, taste, hearing and smell - are benefited by central fixation. All the vital processes - digestion, assimilation, elimination, etc. - are improved by it. The symptoms of functional and organic diseases are relieved. The efficiency of the mind is enormously increased. The benefits of central fixation already observed are, in short, so great that the subject merits further investigation.

CHAPTER XII

PALMING

ALL the methods used in the cure of errors of refraction are simply different ways of obtaining relaxation, and most patients, though by no means all, find it easiest to relax with their eyes shut. This usually lessens the strain to see, and in such cases is followed by a temporary or more lasting improvement in vision.

Most patients are benefited merely by closing the eyes; and by alternately resting them for a few minutes or longer in this way and then opening them and looking at the Snellen test card for a second or less, flashes of improved vision are, as a rule, very quickly obtained. Some temporarily obtain almost normal vision by this means; and in rare cases a complete cure has been effected, sometimes in less than an hour.

But since some light comes through the closed eyelids, a still greater degree of relaxation can be obtained, in all but a few exceptional cases, by excluding it. This is done by covering the closed eyes with the palms of the hands (the fingers being crossed upon the forehead) in such a way as to avoid pressure on the eyeballs. So efficacious is this practice, which I have called "palming," as a means of relieving strain, that we all instinctively resort to it at times, and from it most patients are able to get a considerable degree of relaxation.

But even with the eyes closed and covered in such a way as to exclude all the light, the visual centers of

124 *Palming*

the brain may still be disturbed, the eye may still strain to see; and instead of seeing a field so black that it is impossible to remember, imagine, or see anything blacker, as one ought normally to do when the optic nerve is not subject to the stimulation of light, the patient will see illusions of lights **and colors** ranging all the way from an imperfect black to kaleidoscopic appearances so vivid that they seem to be actually seen with the eyes. The worse the condition of the eyesight, as a rule, the more numerous, vivid and persistent these appearances are. Yet some persons with very imperfect sight are able to palm almost perfectly from the beginning, and are, therefore, very quickly cured. Any disturbance of mind or body, such as fatigue, hunger, anger, worry or depression, also makes it difficult for patients to see black when they palm, persons who can see it perfectly under ordinary conditions being often unable to do so without assistance when they are ill or in pain.

It is impossible to see a perfect black unless the eyesight is perfect, because only when the eyesight is perfect is the mind at rest; but some patients can without difficulty approximate such a black nearly enough to improve their eyesight, and as the eyesight improves the deepness of the black increases. Patients who fail to see even an approximate black when they palm state that instead of black they see

streaks or floating clouds of gray, flashes of light, patches of red, blue, green, yellow, etc. Sometimes instead of an immovable black, clouds of black will be seen moving across the field. In other cases the black will be seen for a few seconds and then some other color will take its place. The different ways in which patients can fail to see black when their eyes are closed and covered are, in fact, very numerous and often very peculiar.

Vivid Colors Seen When Palming 125

Some patients have been so impressed with the vividness of the colors which they imagined they saw that no amount of argument could, or did, convince them that they did not actually see them with their eyes. If

Fig. 42. Palming

This is one of the most effective methods of obtaining relaxation of all the sensory nerves.

other people saw bright lights or colors, with their eyes closed and covered, they admitted that these things would be illusions; but what they themselves saw under the same conditions was reality. They would not believe, until they had themselves demonstrated the truth, that

126 *Palming*

their illusions were due to an imagination beyond their control.

Successful palming in these more difficult cases usually involves the practice of all the methods for improving the sight described in succeeding chapters. For reasons which will be explained in the following chapter, the majority of such patients may be greatly helped by the memory of a black object. They are directed to look at such an object at the distance at which the color can be seen best, close the eyes and remember the color, and repeat until the memory appears to be equal to the sight. Then they are instructed, while still holding the memory of the black, to cover the closed eyes with the palms of the hands in the manner just described. If the memory of the black is perfect, the whole background will be black. If it is not, or if it does not become so in the course of a few seconds, the eyes are opened and the black object regarded again.

Many patients become able by this method to see black almost perfectly for a short time; but most of them, even those whose eyes are not very bad, have great difficulty in seeing it continuously. Being unable to remember black for more than from three to five seconds, they cannot see black for a longer time than this. Such patients are helped by central fixation. When they have become able to see one part of a black object darker than the whole, they are able to remember the smaller area for a longer time than they could the larger one, and thus become able to see black for a longer period when they palm. They are also benefited by mental shifting (see Chapter XV) from one black object to another, or from one part of a black object to another. It is impossible to see, remember, or imagine anything, even for as much as

Mental Shifting! 127

a second, without shifting from one part to another, or to some other object and back again; and the attempt to do so always produces strain. Those who think they are remembering a black object continuously are unconsciously comparing it with something not so black, or

Fig. 43

Patient with atrophy of the optic nerve gets flashes of improved vision after palming.

else its color and its position are constantly changing. It is impossible to remember even such a simple thing as a period perfectly black and stationary for more than a fraction of a second. When shifting is not done unconsciously patients must be encouraged to do it consciously. They may be directed, for instance, to remember successively a black hat, a black shoe, a black velvet dress, a black plush curtain, or a fold in the black dress or the

128 Palming

— . . .

black curtain, holding each one not more than a fraction of a second. Many persons have been benefited by remembering all the letters of the alphabet in turn perfectly black. Others prefer to shift from one small black object, such as a period or a small letter, to another, or to swing such an object in a manner to be described later (see Chapter XV).

In some cases the following method has proved successful: When the patient sees what he thinks is a perfect black, let him remember a piece of starch on this background, and on the starch the letter F as black as the background. Then let him let go of the starch and remember only the F, one part best, on the black background. In a short time the whole field may become as black as the blacker part of the F. The process can be repeated many times with a constant increase of blackness in the field.

In one case a patient who saw grey so vividly when she palmed that she was positive she saw it with her eyes, instead of merely imagining it, was able to obliterate nearly all of it by first imagining a black C on the grey field, then two black C's, and finally a multitude of overlapping C's.

It is impossible to remember black perfectly when it is not seen perfectly. If one sees it imperfectly, the best one can do is to remember it imperfectly. All persons, without exception, who can see or read diamond type at the near-point, no matter how great their myopia may be, or how much the interior of the eye may be diseased, become able, as a rule, to see black with their eyes closed and covered more readily than patients with hypermetropia or astigmatism; because, while myopes cannot see anything perfectly, even at the near-point, they see

Imperfect Memory Useful 129

better at that point than persons with hypermetropia or astigmatism do at any distance. Persons with high degrees of myopia, however, often find palming very difficult, since they not only see black very imperfectly, but, because of the effort they are making to see, cannot remember it more than one or two seconds. Any other condition of the eye which prevents the patient from seeing black perfectly also makes palming difficult. In some cases black is never seen as black, appearing to be grey, yellow, brown, or even bright red. In such cases it is usually best for the patient to improve his sight by other methods before trying to palm. Blind persons usually have more trouble in seeing black than those who can see, but may be helped by the memory of a black object familiar to them before they lost their sight. A blind painter who saw grey continually when he first tried to palm became able at last to see black by the aid of the memory of black paint. He had no perception of light whatever and was in terrible pain; but when he succeeded in seeing black the pain vanished, and when he opened his eyes he saw light.

Even the imperfect memory of black is useful, for by its aid a still blacker black can be both remembered and seen; and this brings still further improvement. For instance, let the patient regard a letter on the Snellen test card at the distance at which the color is seen best, then close his eyes and remember it. If the palming produces relaxation, it will be possible to imagine a deeper shade of black than was seen, and by remembering this black when again regarding the letter it can be seen blacker than it was at first. A still deeper black can then be imagined, and this deeper black can, in turn, be transferred to the letter on the test card. By continuing this

130 Palming

process a perfect perception of black, and hence perfect sight, are sometimes very quickly obtained. The deeper the shade of black obtained with the eyes closed, the more easily it can be remembered when regarding the letters on the test card.

The longer some people palm the greater the relaxation they obtain and the darker the shade of black they are able both to remember and see. Others are able to palm successfully for short periods, but begin to strain if they keep it up too long.

It is impossible to succeed by effort, or by attempting to "concentrate" on the black. As popularly understood, concentration means to do or think one thing only; but this is impossible, and an attempt to do the impossible is a strain which defeats its own end. The human mind is not capable of thinking of one thing only. It can think of one thing best, and is only at rest when it does so; but it cannot think of one thing only. A patient who tried to see black only and to ignore the kaleidoscopic colors which intruded themselves upon her field of vision, becoming worse and worse the more they were ignored, actually went into convulsions from the strain, and was attended every day for a month by her family physician before she was able to resume the treatment. This patient was advised to stop palming, and, with her eyes open, to recall as many colors as possible, remembering each one as perfectly as possible. By thus taking the bull by the horns and consciously making the mind wander more than it did unconsciously, she became able, in some way, to palm for short periods.

Some particular kinds of black objects may be found to be more easily remembered than others. Black plush of a high grade for instance, proved to be an optimum

Optimum Blacks 131

(see Chapter XVIII) with many persons as compared with black velvet, silk, broadcloth, ink and the letters on the Snellen test card, although no blacker than these other blacks. A familiar black object can often be remembered more easily by the patient than those that

Fig. 44

No. 1. - Owing to paralysis of the seventh nerve on the right side, resulting from a mastoid operation on the right ear, the patient is unable to close her lips.

No. 2. - After palming and remembering a perfectly black period she became able not only to close the lips, but to whistle. The cure was permanent.

are less so. A dressmaker, for instance, was able to remember a thread of black silk when she could not remember any other black object.

132 *Palming*

When a black letter is regarded before palming the patient will usually remember not only the blackness of the letter, but the white background as well. If the memory of the black is held for a few seconds, however, the background usually fades away and the whole field becomes black.

Patients often say that they remember black perfectly when they do not. One can usually tell whether or not this is the case by noting the effect of palming upon the vision. If there is no improvement in the sight when the eyes are opened, it can be demonstrated, by bringing the black closer to the patient, that it has not been remembered perfectly.

Although black is, as a rule, the easiest color to remember, for reasons explained in the next chapter, the following method sometimes succeeds when the memory of black fails: Remember a variety of colors - bright red, yellow, green, blue, purple, white especially - all in the most intense shade possible. Do not attempt to hold any of them more than a second. Keep this up for five or ten minutes. Then remember a piece of starch about half an inch in diameter as white as possible. Note the color of the background. Usually it will be a shade of black. If it is, note whether it is possible to remember anything blacker, or to see anything blacker with the eyes open. In all cases when the white starch is remembered perfectly the background will be so black that it will be impossible to remember anything blacker with the eyes closed, or to see anything blacker with them open.

When palming is successful it is one of the best methods I know of for securing relaxation of all the sensory nerves, including those of sight. When perfect relaxa-

When Palming is Successful 133

tion is gained in this way, as indicated by the ability to see a perfect black, it is completely retained when the eyes are opened, and the patient is permanently cured. At the same time pain in the eyes and head,

and even in other parts of the body, is permanently relieved. Such cases are very rare, but they do occur. With a lesser

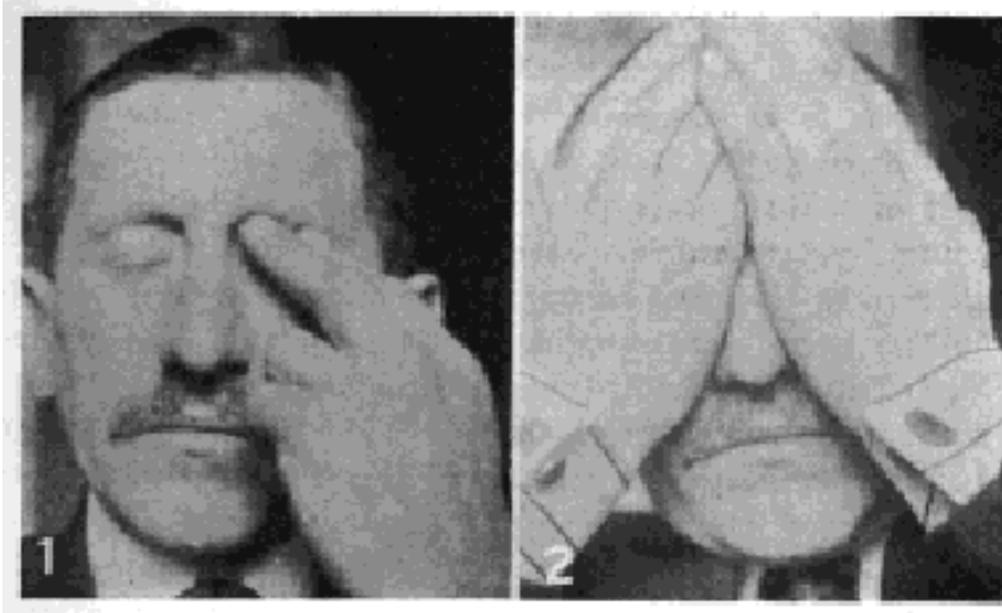

Fig. 45

Fig. 1. - Patient with absolute glaucoma of the right eye. He had suffered agonizing pain *for* six months and had no perception of light. He was photographed when testing the tension of his eyeball, which he found to be perfectly hard.

Fig. 2. - The patient is palming and remembering a perfectly black period. After half an hour the eyeball became soft the pain ceased, and the patient became able to see the light. After three years there was no return of the glaucoma.

degree of relaxation much of it is lost when the eyes are opened, and what is retained is not held permanently. In other words, the greater the degree of the relaxation produced by palming the more of it is retained when the

134 Palming

eyes are opened and the longer it lasts. If you palm perfectly, you retain, when you open your eyes, all of the relaxation that you gain, and you do not lose it again. If you palm imperfectly, you retain only part of what you gain and retain it only temporarily - it may be only for a few moments. Even the smallest degree of relaxation is useful, however, for by means of it a still greater degree may be obtained.

Patients who succeed with palming from the beginning are to be congratulated, for they are always cured

very quickly. A very remarkable case of this kind was that of a man nearly seventy years of age with compound hypermetropic astigmatism and presbyopia, complicated by incipient cataract. For more than forty years he had worn glasses to improve his distant vision, and for twenty years he had worn them for reading and desk work. Because of the cloudiness of the lens, he had now become unable to see well enough to do his work, even with glasses; and the other physicians whom he had consulted had given him no hope of relief except by operation when the cataract was ripe. When he found palming helped him, he asked:

"Can I do that too much?"

"No," he was told. "Palming is simply a means of resting your eyes, and you cannot rest them too much."

A few days later he returned and said:

"Doctor, it was tedious, very tedious; but I did it."

"What was tedious?" I asked.

"Palming," he replied. "I did it continuously for twenty hours."

"But you couldn't have kept it up for twenty hours continuously," I said incredulously. "You must have stopped to eat."

Tedious But Worth While 135

And then he related that from four o'clock in the morning until twelve at night he had eaten nothings only drinking large quantities of water, and had devoted practically all of the time to palming. It must have been tedious, as he said, but it was also worth while. When he looked at the test card, without glasses, he read the bottom line at twenty feet. He also read fine print at six inches and at twenty. The cloudiness of the lens had become much less, and in the center had entirely disappeared. Two years later there had been no relapse.

Although the majority of patients are helped by palming, a minority are unable to see black, and only increase their strain by trying to get relaxation in this way. In most cases it is possible, by using some or all of the various methods outlined in this chapter, to enable the patient to palm successfully; but if much difficulty is experienced, it is usually better and more expeditious to drop the method until the sight has been improved by other means. The patient may then become able to see black when he palms, but some never succeed in doing it until they are cured.

CHAPTER XIII

MEMORY AS AN AID TO VISION

WHEN the mind is able to remember perfectly any phenomenon of the senses, it is always perfectly relaxed. The sight is normal, if the eyes are open; and when they are closed and covered so as to exclude all the light, one sees a perfectly black field - that is nothing at all. If you can remember the ticking of a watch, or an odor or a taste perfectly, your mind is perfectly at rest, and you will see a perfect black when your eyes are closed and covered. If your memory of a sensation of touch could be equal to the reality, you would see nothing but black when the light was excluded from your eyes. If you were to remember a bar of music perfectly when your eyes were closed and covered, you would see nothing but black. But in the case of any of these phenomena it is not easy to test the correctness of the memory, and the same is true of colors other than black. All other colors, including white, are altered by the amount of light to which they are exposed, and are seldom seen as perfectly as it is possible for the normal eye to see them. But when the sight is normal, black is just as black in a dim light as in a bright one. It is also just as black at the distance as at the near-point, while a small area is just as black as a large one, and, in fact, appears blacker. Black is, moreover, more readily 136

Memory a Measure of Relaxation 137

available than any other color. There is nothing blacker than printer's ink, and that is practically ubiquitous. By means of the memory of black, therefore, it is possible to measure accurately one's own relaxation. If the color is remembered perfectly, one is perfectly relaxed. If it is remembered almost perfectly, one's relaxation is almost perfect. If it cannot be remembered at all, one has very little or no relaxation.

By means of simultaneous retinoscopy, these facts can be readily demonstrated. An absolutely perfect memory is very rare, so much so that it need hardly be taken into consideration; but a practically perfect memory, or what might be called normal, is attainable by every one under certain conditions. With such a memory of black, the retinoscope shows that all errors of refraction are corrected. If the memory is less than normal, the contrary will be the case. If it fluctuates, the shadow of the retinoscope will fluctuate. The testimony of the retinoscope is, in fact, more reliable than the statements of the patient. Patients often believe and state that they remember black perfectly, or normally, when the retinoscope indicates an error of refraction; but in such cases it can usually be demonstrated by bringing the test card to the point at which the black letters can be seen best, that the memory is not equal to the sight. That the color cannot be remembered perfectly when the eyes and mind are under a strain, the reader can easily demonstrate by trying to remember it when making a conscious effort to see - by staring, partly closing the eyes, frowning, etc - or while trying to see all the letters of a line equally well at one time. It will be found that it either cannot be remembered at all under these conditions, or that it is remembered very imperfectly.

138 Memory as an Aid to Vision

When the two eyes of a patient are different, it has been found that the difference can be exactly measured by the length of time a black period can be remembered, while looking at the Snellen test card, with both eyes open, and with the better eye closed. A patient with normal vision in the right eye and half-normal vision in the left could, when looking at the test card with both eyes open, remember a period for twenty seconds continuously; but with the better eye closed, it could be remembered only ten seconds. A patient with half-normal vision in the right eye and one-quarter normal in the left could remember a period twelve seconds with both eyes open, and only six seconds with the better eye closed. A third patient, with normal sight in the right eye and vision of one-tenth in the left, could remember a period twenty seconds with both eyes open, and only two seconds when the better eye was closed. In other words, if the right eye is better than the left, the memory is better when the right eye is open than when only the left eye is open, the difference being in exact proportion to the difference in the vision of the two eyes.

In the treatment of functional eye troubles this relationship between relaxation and memory is of great practical importance. The sensations of the eye and of the mind supply very little information as to the strain to which both are being subjected, those who strain most often suffering the least discomfort; but by means of his ability to remember black the patient can always know whether he is straining or not, and is able, therefore, to avoid the conditions that produce strain. Whatever method of improving his sight the patient is using, he is advised to carry with him constantly the memory of a small area of black, such as a period, so that

Not Attainable by Effort 139

he may recognize and avoid the conditions that produce strain, and in some cases patients have obtained a complete cure in a very short time by this means alone. One advantage of the method is that it does not require a test card, for at any hour of the day or night, whatever the patient may be doing, he can always place himself in the conditions favorable to the perfect memory of a period.

The condition of mind in which a black period can be remembered cannot be attained by any sort of effort. The memory is not the cause of the relaxation, but must be preceded by it. It is obtained only during moments of relaxation, and retained only as long as the causes of strain are avoided; but how this is accomplished cannot be fully explained, just as many other psychological phenomena cannot be explained. We only know that under certain conditions that might be called favorable a degree of relaxation sufficient for the memory of a black period is possible, and that, by persistently seeking these condition, the patient becomes able to increase the degree of the relaxation and prolong its duration, and finally becomes able to retain it under unfavorable conditions.

For most patients palming provides the most favorable conditions for the memory of black. When the strain to see is lessened by the exclusion of the light, the patient usually becomes able to remember a black object for a few seconds or longer, and this period of relaxation can be prolonged in one of two ways. Either the patient can open his eyes and look at a black object by central fixation at the distance at

which it can be seen best, and at which the eyes are, therefore, most relaxed, or he can shift mentally from one black object to

140 Memory as an Aid to Vision

another, or from one part of a black object to another. By these means, and perhaps also through other influences that are not clearly understood, most patients become able, sooner or later, to remember black for an indefinite length of time with their eyes closed and covered.

With the eyes open and looking at a blank surface without trying consciously to see, the unconscious strain is lessened so that the patient becomes able to remember a black period, and all errors of refraction, as demonstrated by the retinoscope, are corrected. This result has been found to be invariable, and so long as the surface remains blank and the patient does not begin to remember or imagine things seen imperfectly, the memory and the vision may be retained. But if, with the improved vision, details upon the surface begin to come out, or if the patient begins to think of the test card, which he has seen imperfectly, the strain to see will return and the period will be lost.

When looking at a surface on which there is nothing particular to see, distance makes no difference to the memory, because the patient can always look at such a surface, no matter where it is, without straining to see it. When looking at letters, or other details, however, the memory is best at the point at which the patient's sight is best, because at that point the eyes and mind are more relaxed than when the same letters or objects are regarded at distances at which the vision is not so good. By practicing central fixation at the most favorable distance, therefore, and using any other means of improving the vision which are found effectual, the memory of the period may be improved, in some cases, very rapidly.

If the relaxation gained under these favorable condi

Improved Sight a Disturbing Influence 141

tions is perfect, the patient will be able to retain it when the mind is conscious of the impressions of sight at unfavorable distances. Such cases are, however, very rare. Usually the degree of relaxation gained is markedly imperfect, and is, therefore, lost to a greater or less degree when the conditions are unfavorable, as when letters or objects are being regarded at unfavorable distances. So disturbing are the impressions of sight under these circumstances, that just as soon as details begin to come out at distances at which they have not previously been seen, the patient usually loses his relaxation, and with it the memory of the period. In fact, the strain to see may even return before he has had time to become conscious of the image on his retina, as the following case strikingly illustrates:

A woman of fifty-five who had myopia of fifteen diopters, complicated with other conditions which made it impossible for her to see the big C at more than one foot, or to go about, either in her house or on the

street, without an attendant, became able, when she looked at a green wall without trying to see it, to remember a perfectly black period and to see a small area of the wall-paper at the distance as well as she could at the near-point. When she had come close to the wall, she was asked to put her hand on the door-knob, which she did without hesitation. "But I don't see the knob," she hastened to explain. As a matter of fact she had seen it long enough to put her hand on it; but as soon as the idea of seeing it was suggested to her she lost the memory of the period, and with it her improved vision, and when she again tried to find the knob she could not do so.

When a period is remembered perfectly while a let

142 Memory as an Aid to Vision

ter on the Snellen test card is being regarded, the letter improves, with or without the consciousness of the patient; because it is impossible to strain and relax at the same time, and if one relaxes sufficiently to remember the period, one must also relax sufficiently to see the letter, consciously or unconsciously. Letters on either side of the one regarded, or on the lines above and below it, also improve. When the patient is conscious of seeing the letters, this is very distracting, and usually causes him, at first, to forget the period; while with some patients, as already noted the strain may return even before the letters are consciously recognized.

Thus patients find themselves on the horns of a dilemma. The relaxation indicated by the memory of a period improves their sight, and the things they see with this improved vision cause them to lose their relaxation and their memory. It is very remarkable to me how the difficulty is ever overcome, but some patients are able to do it in five minutes or half an hour. With: others the process is long and tedious.

There are various ways of helping patients to deal with this situation. One is to direct them to remember the period while looking a little to one side of the test card, say a foot or more; then to look a little nearer to it, and finally to look between the lines. In this way they may become able to see the letters in the eccentric field without losing the period; and when they can do this they may become able to go a step farther, and look directly at a letter without losing control of their memory. If they cannot do it, they are told to look at only one part of a letter - usually the bottom - or to see or imagine the period as part of the letter, while noting that the rest of the letter is less black and less distinct than the part

Dodging Improved Sight 143

directly regarded- When they can do this they become able to remember the period better than when the letter is seen all alike. If the letter is seen all alike, the perfect memory of the period is always lost. The next step is to ask the patient to note whether the bottom of the letter is straight, curved, or open, without losing the period on the bottom. When he can do this, he is asked to do the same with the sides and top of the letter, still holding the period on the bottom. Usually when the parts can be observed separately in this way, the whole letter can be seen without losing the memory of the period; but it occasionally happens

that this is not the case, and further practice is needed before the patient can become conscious of all sides of the letter at once without losing the period. This may require moments, hours, days, or months. In one case the following method succeeded:

The patient, a man with fifteen diopters of myopia, was so much disturbed by what he saw when his vision had been improved by the memory of a period that he was directed to look away from the Snellen test card, or whatever object he was regarding, when he found the letters or other details coming out; and for about a week he went around persistently dodging his improved sight. As his memory improved, it became more and more difficult for him to do this, and at the end of the week it was impossible. When he looked at the bottom line at a distance of twenty feet he remembered the period perfectly, and when asked if he could see the letters, he replied:

"I cannot help but see them."

Some patients retard their recovery by decorating the scenery with periods as they go about during the day,

144 Memory as an Aid to Vision

instead of simply remembering a period in their minds. This does them no good, but is, on the contrary, a cause of strain. The period can be imagined perfectly and with benefit as forming part of a black letter on the test card, because this merely means imagining that one sees one part of the black letter best; but it cannot be imagined perfectly on any surface which is not black, and to attempt to imagine it on such surfaces defeats the end in view.

The smaller the area of black which the patient is able to remember, the greater is the degree of relaxation indicated; but some patients find it easier, at first, to remember a somewhat larger area, such as one of the letters on the Snellen test card with one part blacker than the rest. They may begin with the big C, then proceed to the smaller letters, and finally get to a period. It is then found that this small area is remembered more easily than the larger ones, and that its black is more intense. Instead of a period, some patients find it easier to remember a colon, with one period blacker than the other, or a collection of periods, with one blacker than all the others, or the dot over an i or j. Others, again, prefer a comma to a period. In the beginning most patients find it helpful to shift consciously from one of these black areas to another, or from one part of such an area to another, and to realize the swing, or pulsation, produced by such shifting (see Chapter XV); but when the memory becomes perfect, one object may be held continuously, without conscious shifting, while the swing is realized only when attention is directed to the matter.

Although black is, as a rule, the best color to remember, some patients are bored or depressed by it, and prefer to remember white or some other color. A

A Help to Other Mental Processes 145

familiar object, or one with pleasant associations, is often easier to remember than one which has no particular interest. One patient was cured by the memory of a yellow buttercup, and another was able to remember the opal of her ring when she could not remember a period. Whatever the patient finds easiest to remember is the best to remember, because the memory can never be perfect unless it is easy.

When the memory of the period becomes habitual, it is not only not a burden, but is a great help to other mental processes. The mind, when it remembers one thing better than all other things, possesses central fixation, and its efficiency is thereby increased, just as the efficiency of the eye is increased by central fixation. In other words, the mind attains its greatest efficiency when it is at rest, and it is never at rest unless one thing is remembered better than all other things. When the mind is in such a condition that a period is remembered perfectly, the memory for other things is improved.

A high-school girl reports that when she was unable to remember the answer to a question in an examination, she remembered the period, and the answer came to her. When I cannot remember the name of a patient, I remember a period - and, behold, I have it! A musician who had perfect sight and could remember a period perfectly, had a perfect memory for music; but a musician with imperfect sight who could not remember a period could play nothing without his notes, only gaining that power when his sight and visual memory had become normal. In some exceptional cases, the strain to see letters on the Snellen test card has been so terrific that patients have said that they not only could not remem

146 Memory as an Aid to Vision

ber a period while they were looking at them, but could not remember even their own names.

Patients may measure the accuracy of their memory of the period, not only by comparing it with the sight, but by the following tests:

When the memory of the period is perfect it is instantaneous. If a few seconds or longer are necessary to obtain the memory, it is never perfect.

A perfect memory is not only instantaneous, but continuous.

When the period is remembered perfectly perfect sight comes instantaneously. If good vision is obtained only after a second or two, it can always be demonstrated that the memory of the period is imperfect and the sight also.

The memory of a period is a test of relaxation. It is the evidence by which the patient knows that his eyes and mind are at rest. It may be compared to the steam-gauge of an engine, which has nothing to do with the machinery, but is of great importance in giving information as to the ability of the mechanism to do its work. When the period is black one knows that the engine of the eye is in good working order. When the period fades, or is lost, one knows that it is out of order, until a cure is effected. Then one does not need a period, or any other aid to vision, just as the engineer does not need a steam-gauge when the engine is going properly. One patient who had gained telescopic and microscopic vision by the methods presented in this book said, in answer to an inquiry from some one interested in investigating the treatment of errors of refraction without glasses, that he had not only done nothing to prevent a relapse, but had even forgotten how he was cured.

The Period no Longer Needed 147

The reply was unsatisfactory to the inquirer, but is quoted to illustrate the fact that when a patient is cured he does not need to do anything consciously in order to stay cured, although the treatment can always be continued with benefit, since even supernormal vision can be improved.

CHAPTER XIV

IMAGINATION AS AN AID TO VISION

WE see very largely with the mind, and only partly with the eyes. The phenomena of vision depend upon the mind's interpretation of the impression upon the retina. What we see is not that impression, but our own interpretation of it. Our impressions of size, color, form and location can be demonstrated to depend upon the interpretation by the mind of the retinal picture. The moon looks smaller at the zenith than it does at the horizon, though the optical angle is the same and the impression on the retina may be the same, because at the horizon the mind unconsciously compares the picture with the pictures of surrounding objects, while at the zenith there is nothing to compare it with. The figure of a man on a high building, or on the topmast of a vessel, looks small to the landsman; but to the sailor it appears to be of ordinary size, because he is accustomed to seeing the human figure in such positions.

Persons with normal vision use their memory, or imagination, as an aid to sight; and when the sight is imperfect it can be demonstrated, not only that the eye itself is at fault, but that the memory and imagination are impaired, so that the mind adds imperfections to the imperfect retinal image. No two persons with normal sight will get the same visual impressions from the same object; for their interpretations of the retinal picture will differ as much as their individualities differ, and

148

The Mind Out of Focus 149

when the sight is imperfect the interpretation is far more variable. It reflects, in fact, the loss of mental control which is responsible for the error of refraction. When the eye is out of focus, in short, the mind is also out of focus.

According to the accepted view most of the abnormalities of vision produced when there is an error of refraction in the eye are sufficiently accounted for by the existence of that error. Some are supposed to be due to diseases of the brain or retina. Multiple images are attributed to astigmatism, though only two can be legitimately accounted for in this way, while some patients state that they see half a dozen or more, and many persons with astigmatism do not see any. It can easily be demonstrated, however, that the inaccuracy of the focus accounts for only a small part of these results; and since they can all be corrected in a few seconds through the correction, by relaxation, of the error of refraction, it is evident that they cannot be due to any organic disease.

If we compare the picture on the glass screen of the camera when the camera is out of focus with the visual impressions of the mind when the eye is out of focus, there will be found to be a great difference between them. When the camera is out of focus it turns black into grey, and blurs the outlines of the picture; but it produces these results uniformly and constantly. On the screen of the camera an imperfect picture of a black letter would be equally imperfect in all parts, and the same adjustment of the focus

would always produce the same picture. But when the eye is out of focus the imperfect picture which the patient imagines that he sees is always changing, whether the focus changes or

150 Imagination as an Aid to Vision

not. There will be more grey on one part than on another, and both the shade and the position of the grey may vary within wide limits in a very short space of time. One part of the letter may appear grey and the rest black. Certain outlines may be seen better than others, the vertical lines, perhaps, appearing black and the diagonal grey, and vice versa. Again, the black may be changed into brown, yellow, green, or even red, transmutations impossible to the camera. Or there may be spots of color, or of black, on the grey, or on the white openings. There may also be spots of white, or of color, on the black.

When the camera is out of focus the picture which it produces of any object is always slightly larger than the image produced when the focus is correct; but when the eye is out of focus the picture which the mind sees may be either larger or smaller than it normally would be. To one patient the big C at ten feet appeared smaller than at either twenty feet or four inches. To some it appears larger than it actually is at twenty feet, and to others it seems smaller.

When the human eye is out of focus the form of the objects regarded by the patient frequently appears to be distorted, while their location may also appear to change. The image may be doubled, tripled, or still further multiplied, and while one object, or part of an object may be multiplied other objects or parts of objects in the field of vision may remain single. The location of these multiple images is sometimes constant and at others subject to continual change. Nothing like this could happen when the camera is out of focus.

If two cameras are out of focus to the same degree, they will take two imperfect pictures exactly alike. If

Hot Imagination Cures 151

two eyes are out of focus to the same degree, similar impressions will be made upon the retina of each; but the impressions made upon the mind may be totally unlike, whether the eyes belong to the same person or to different persons. If the normal eye looks at an object through glasses that change its refraction, the greyness and blurring produced are uniform and constant; but when the eye has an error of refraction equivalent to that produced by the glasses, these phenomena are nonuniform and variable.

It is fundamental that the patient should understand that these aberrations of vision - which are treated more fully in a later chapter - are illusions, and not due to a fault of the eyes. When he knows that a thing is an illusion he is less likely to see it again. When he becomes convinced that what he sees is imaginary it helps to bring the imagination under control; and since a perfect imagination is impossible without perfect relaxation, a perfect imagination not only corrects the false interpretation of the retinal image, but corrects the error of refraction.

Imagination is closely allied to memory, although distinct from it. Imagination depends upon the memory, because a thing can be imagined only as well as it can be remembered. You cannot imagine a sunset unless you have seen one; and if you attempt to imagine a blue sun, which you have never seen, you will become myopic, as indicated by simultaneous retinoscopy. Neither imagination nor memory can be perfect unless the mind is perfectly relaxed. Therefore when the imagination and memory are perfect, the sight is perfect. Imagination, memory and sight are, in fact, coincident. When one is perfect, all are perfect, and when

152 Imagination as an Aid to Vision

one is imperfect, all are imperfect. If you imagine a letter perfectly, you will see the letter and other letters in its neighborhood will come out more distinctly, because it is impossible for you to relax and imagine you see a perfect letter and at the same time strain and actually see an imperfect one. If you imagine a perfect period on the bottom of a letter, you will see the letter perfectly, because you cannot take the mental picture of a perfect period and put it on an imperfect letter. It is possible, however, as pointed out in the preceding chapter, for sight to be unconscious. In some cases patients may imagine the period perfectly, as demonstrated by the retinoscope, without being conscious of seeing the letter; and it is often some time before they are able to be conscious of it without losing the period.

When one treats patients who are willing to believe that the letters can be imagined, and who are content to imagine without trying to see, or compare what they see with what they imagine, which always brings back the strain, very remarkable results are sometimes obtained by the aid of the imagination. Some patients at once become able to read all the letters on the bottom line of the test card after they become able to imagine that they see one letter perfectly black and distinct. The majority, however, are so distracted by what they see when their vision has been improved by their imagination that they lose the latter. It is one thing to be able to imagine perfect sight of a letter, and another to be able to see the letter and other letters without losing control of the imagination.

In myopia the following method is often successful:

First look at a letter at the point at which it is seen best. Then close the eyes and remember it. Repeat

Patients Who Succeed 153

until the memory is almost as good as the sight at the nearpoint. With the test card at a distance of twenty feet, look at a blank surface a foot or more to one side of it, and again remember the letter. Do the same at six inches and at three inches. At the last point note the appearance of the letters on the card - that is, in the eccentric field. If the memory is still perfect, they will appear to be a dim black, not grey, and those nearest the point of fixation will appear blacker than those more distant. Gradually reduce the distance

between the point of fixation and the letter until able to look straight at it and imagine that it is seen as well as it is remembered. Occasionally it is well during the practice to close and cover the eyes and remember the letter, or a period, perfectly black. The rest and mental control gained in this way are a help in gaining control when one looks at the test card.

Patients who succeed with this method are not conscious while imagining a perfect letter, of seeing, at the same time, an imperfect one, and are not distracted when their vision is improved by their imagination. Many patients can remember perfectly with their eyes closed, or when they are looking at a place where they cannot see the letter; but just as soon as they look at it they begin to strain and lose control of their memory. Therefore, as the imagination depends upon the memory, they cannot imagine that they see the letter. In such cases it has been my custom to proceed somewhat in the manner described in the preceding chapter. I begin by saying to the patient:

"Can you imagine a black period on the bottom of this letter, and at the same time, while imagining the period perfectly, are you able to imagine that you see the letter?"

154 Imagination as an Aid to Vision

Sometimes they are able to do this, but usually they are not. In that case they are asked to imagine part of the letter, usually the bottom. When they have become able to imagine this part straight, curved, or open, as the case may be, they become able to imagine the sides and top, while still holding the period on the bottom. But even after they have done this, they may still not be able to imagine the whole letter without losing the period. One may have to coax them along by bringing the card up a little closer, then moving it farther away; for when looking at a surface where there is anything to see, the imagination improves in proportion as one approaches the point where the sight is best, because at that point the eyes are most relaxed. When there is nothing particular to see, the distance makes no difference, because no effort is being made to see.

To encourage patients to imagine they see the letter it seems helpful to keep saying to them over and over again:

"Of course you do not see the letter. I am not asking you to see it. I am just asking you to imagine that you see it perfectly black and perfectly distinct."

When patients become able to see a known letter by the aid of their imagination, they become able to apply the same method to an unknown letter; for just as soon as any part of a letter, such as an area equal to a period, can be imagined to be perfectly black, the whole letter is seen to be black, although the visual perception of this fact may not, at first, last long enough for the patient to become conscious of it.

In trying to distinguish unknown letters, the patient discovers that it is impossible to imagine perfectly unless one imagines the truth; for if a letter, or any part

of a letter, is imagined to be other than it is, the mental picture is foggy and inconstant, just like a letter which is seen imperfectly.

The ways in which the imagination can be interfered with are very numerous. There is one way of imagining perfectly and an infinite number of ways of imagining imperfectly. The right way is easy. The mental picture of the thing imagined comes as quick as thought, and can be held more or less continuously. The wrong way is difficult. The picture comes slowly, and is both variable and discontinuous. This can be demonstrated to the patient by asking him first to imagine or remember a black letter as perfectly as possible with the eyes closed, and then to imagine the same letter imperfectly. The first he can usually do easily; but it will be found very difficult to imagine a black letter with clear outlines to be grey, with fuzzy edges and clouded openings, and impossible to form a mental picture of it that will remain constant for an appreciable length of time. The letter will vary in color, shape and location in the visual field, precisely as a letter does when it is seen imperfectly; and just as the strain of imperfect sight produces discomfort and pain, the effort to imagine imperfectly will sometimes produce pain. The more nearly perfect the mental picture of the letter, on the contrary, the more easily and quickly it comes and the more constant it is.

Some very dramatic cures have been effected by means of the-imagination. One patient, a physician, who had worn glasses for forty years and who could not without them see the big C at twenty feet, was cured in fifteen minutes simply by imagining that he saw the letters black. When asked to describe the big C with unaided

156 Imagination as an Aid to Vision

vision he said it looked grey to him, and that the opening was obscured by a grey cloud to such an extent that he had to guess that it had an opening. He was told that the letter was black, perfectly black, and that the opening was perfectly white, with no grey cloud; and the card was brought close to him so that he could see that this was so. When he again regarded the letter at the distance, he remembered its blackness so vividly that he was able to imagine that he saw it just as black as he had seen it at the near-point, with the opening perfectly white; and therefore he saw the letter on the card perfectly black and distinct. In the same way he became able to read the seventy line; and so he went down the card, until in about five minutes he became able to read at twenty feet the line which the normal eye is supposed to read at ten feet. Next diamond type was given to him to read. The letters appeared grey to him, and he could not read them. His attention was called to the fact that the letters were really black, and immediately he imagined that he saw them black and became able to read them at ten inches.

The explanation of this remarkable occurrence is simply relaxation. All the nerves of the patient's body were relaxed when he imagined that he saw the letters black, and when he became conscious of seeing the letters on the card, he still retained control of his imagination. Therefore he did not begin to strain again, and actually saw the letters as black as he imagined them.

The patient not only had no relapse, but continued to improve. About a year later I visited him in his office and asked him how he was getting on. He replied that his sight was perfect, both for distance and the near-point. He could see the motor cars on the

Too Good to be True 157

other side of the Hudson River and the people in them, and he could read the names of boats on the river which other people could make out only with a telescope. At the same time he had no difficulty in reading the newspapers, and to prove the latter part of this statement, he picked up a newspaper and read a few sentences aloud. I was astonished, and asked him how he did it.

"I did what you told me to do," he said.

"What did I tell you to do?" I asked.

"You told me to read the Snellen test card every day, which I have done, and to read fine print every day in a dim light, which I have also done."

Another patient, who had a high degree of myopia complicated with atrophy of the optic nerve, and who had been discouraged by many physicians, was benefited so wonderfully and rapidly by the aid of his imagination that one day while in the office he lost control of himself completely, and raising a test card which he held in his hand, he threw it across the room.

"It is too good to be true," he exclaimed; "I cannot believe it. The possibility of being cured and the fear of disappointment are more than I can stand."

He was calmed down with some difficulty and encouraged to continue. Later he became able to read the small letters on the test card with normal vision. He was then given fine print to read. When he looked at the diamond type, he at once said that it was impossible for him to read it. However, he was told to follow the same procedure that had benefited his distance sight. That is, he was to imagine a period on one part of the small letters while holding the type at six inches. After testing his memory of the period a number of times, he became able to imagine he saw a period perfectly black

158 Imagination as an Aid to Vision

on one of the small letters. Then he lost control of his nerves again, and on being asked, "What is the trouble?" he said:

"I am beginning to read the fine print, and I am so overwhelmed that I lose my self-control."

In another case, that of a woman with high myopia complicated with incipient cataract, the vision improved in a few days from 3/200 to 20/50. Instead of going gradually down the card, a jump was made from the fifty line to the ten line. The card was brought up close to her, and she was asked to look at the letter O at three inches, the distance at which she saw it best, to imagine that she saw a period on the bottom of it and that the bottom was the blackest part. When she was able to do this at the near-point, the distance was gradually increased until she became able to see the O at three feet. Then I placed the card at ten feet and she exclaimed:

"Oh, doctor, it is impossible! The letter is too small. It is too great a thing for me to do. Let me try a larger letter first."

Nevertheless she became able in fifteen minutes to read the small O on the ten line at twenty feet.

CHAPTER XV

SHIFTING AND SWINGING

WHEN the eye with normal vision regards a letter either at the nearpoint or at the distance, the letter may appear to pulsate, or to move in various directions, from side to side, up and down, or obliquely. When it looks from one letter to another on the Snellen test card, or from one side of a letter to another, not only the letter, but the whole line of letters and the whole card, may appear to move from side to side. This apparent movement is due to the shifting of the eye, and is always in a direction contrary to its movement. If one looks at the top of a letter, the letter is below the line of vision, and, therefore, appears to move downward. If one looks at the bottom, the letter is above the line of vision and appears to move upward. If one looks to the left of the letter, it is to the right of the line of vision and appears to move to the right. If one looks to the right, it is to the left of the line of vision and appears to move to the left.

Persons with normal vision are rarely conscious of this illusion, and may have difficulty in demonstrating it; but in every case that has come under my observation they have always become able, in a longer or shorter time, to do so. When the sight is imperfect the letters may remain stationary, or even move in the same direction as the eye.

It is impossible for the eye to fix a point longer than a fraction of a second. If it tries to do so, it begins to

160 Shifting and Swinging

strain and the vision is lowered. This can readily be demonstrated by trying to hold one part of a letter for an appreciable length of time. No matter how good the sight, it will begin to blur, or even disappear, very quickly, and sometimes the effort to hold it will produce pain. In the case of a few exceptional people a point may appear to be held for a considerable length of time; the subjects themselves may think that they are holding it; but this is only because the eye shifts unconsciously, the movements being so rapid that objects seem to be seen all alike simultaneously.

The shifting of the eye with normal vision is usually not conspicuous, but by direct examination with the

ophthalmoscope it can always be demonstrated. If one eye is examined with this instrument while the other is regarding a small area straight ahead, the eye being examined, which follows the movements of the other, is seen to move in various directions, from side to side, up and down in an orbit which is usually variable. If the vision is normal these movements are extremely rapid and unaccompanied by any appearance of effort. The shifting of the eye with imperfect sight, on the contrary, is slower, its excursions are wider, and the movements are jerky and made with apparent effort.

It can also be demonstrated that the eye is capable of shifting with a rapidity which the ophthalmoscope cannot measure. The normal eye can read fourteen letters on the bottom line of a Snellen test card, at a distance of ten or fifteen feet, in a dim light, so rapidly that they seem to be seen all at once. Yet it can be demonstrated that in order to recognize the letters under these conditions it is necessary to make about four shifts to each letter. At the near-point, even though one part of the

160

Rapidity of Eye's Motion 161

letter is seen best, the rest may be seen well enough to be recognized; but at the distance it is impossible to recognize the letters unless one shifts from the top to the bottom and from side to side. One must also shift from one letter to another, making about seventy shifts in a fraction of a second.

A line of small letters on the Snellen test card may be less than a foot long by a quarter of an inch in height; and if it requires seventy shifts to a fraction of a second to see it apparently all at once, it must require many thousands to see an area of the size of the screen of a moving picture, with all its detail of people, animals, houses, or trees, while to see sixteen such areas to a second, as is done in viewing moving pictures, must require a rapidity of shifting that can scarcely be realized. Yet it is admitted that the present rate of taking and projecting moving pictures is too slow. The results would be more satisfactory, authorities say, if the rate were raised to twenty, twenty-two, or twenty-four a second.

The human eye and mind are not only capable of this rapidity of action, and that without effort or strain, but it is only when the eye is able to shift thus rapidly that eye and mind are at rest, and the efficiency of both at their maximum. It is true that every motion of the eye produces an error of refraction; but when the movement is short, this is very slight, and usually the shifts are so rapid that the error does not last long enough to be detected by the retinoscope, its existence being demonstrable only by reducing the rapidity of the movements to less than four or five a second. The period during which the eye is at rest is much longer than that during which an error of refraction is produced. Hence, when

162 Shifting and Swinging

the eye shifts normally no error of refraction is manifest. The more rapid the unconscious shifting of the eye, the better the vision; but if one tries to be conscious of a too rapid shift, a strain will be produced.

Perfect sight is impossible without continual shifting, and such shifting is a striking illustration of the mental control necessary for normal vision. It requires perfect mental control to think of thousands of things in a fraction of a second; and each point of fixation has to be thought of separately, because it is impossible to think of two things, or of two parts of one thing, perfectly at the same time. The eye with imperfect sight tries to accomplish the impossible by looking fixedly at one point for an appreciable length of time; that is, by staring. When it looks at a strange letter and does not see it, it keeps on looking at it in an effort to see it better. Such efforts always fail, and are an important factor in the production of imperfect sight.

One of the best methods of improving the sight, therefore, is to imitate consciously the unconscious shifting of normal vision and to realize the apparent motion produced by such shifting. Whether one has imperfect or normal sight, conscious shifting and swinging are a great help and advantage to the eye; for not only may imperfect sight be improved in this way, but normal sight may be improved also. When the sight is imperfect, shifting, if done properly, rests the eye as much as palming, and always lessens or corrects the error of refraction.

The eye with- normal sight never attempts to hold a point more than a fraction of a second, and when it shifts, as explained in the chapter on "Central Fixation," it always sees the previous point of fixation worse. When it ceases to shift rapidly and to see the point

The Shift That Rests 163

shifted from worse, the sight ceases to be normal, the swing being either prevented or lengthened, or (occasionally) reversed. These facts are the keynote of the treatment by shifting.

In order to see the previous point of fixation worse, the eye with imperfect sight has to look farther away from it than does the eye with normal sight. If it shifts only a quarter of an inch, for instance, it may see the previous point of fixation as well as or better than before; and instead of being rested by such a shift, its strain will be increased, there will be no swing, and the vision will be lowered. At a couple of inches it may be able to let go of the first point; and if neither point is held more than a fraction of a second, it will be rested by such a shift and the illusion of swinging may be produced. The shorter the shift the greater the benefit; but even a very long shift - as much as three feet or more - is a help to those who cannot accomplish a shorter one. When the patient is capable of a short shift, on the contrary, the long shift lowers the vision. The swing is an evidence that the shifting is being done properly, and when it occurs the vision is always improved. It is possible to shift without improvement; but it is impossible to produce the illusion of a swing without improvement, and when this can be done with a long shift, the movement can gradually be shortened until the patient can shift from the top to the bottom of the smallest letter, on the Snellen test card or elsewhere, and maintain the swing. Later he may become able to be conscious of the swinging of the letters without conscious shifting.

No matter how imperfect the sight, it is always possible to shift and produce a swing, so long as the pre

164 Shifting and Swinging

vious point of fixation is seen worse. Even diplopia and polyopia I do not prevent swinging with some improvement of vision. Usually the eye with imperfect vision is able to shift from one side of the card to the other, or from a point above the card to a point below it, and observe that in the first case the card appears to move from side to side, while in the second it appears to move up and down.

When patients are suffering from high degrees of eccentric fixation, it may be necessary, in order to help them to see worse when they shift, to use some of the methods described in the chapter on "Central Fixation." Usually, however, patients who cannot see worse when they shift at the distance can do it readily at the near-point, as the sight is best at that point, not only in myopia, but often in hypermetropia as well. When the swing can be produced at the near point, the distance can be gradually increased until the same thing can be done at twenty feet.

After resting the eyes by closing or palming, shifting and swinging are often more successful. By this method of alternately resting the eyes and then shifting, persons with very imperfect sight have sometimes obtained a temporary or permanent cure in a few weeks.

Shifting may be done slowly or rapidly, according to the state of the vision. At the beginning the patient will be likely to strain if he shifts too rapidly; and then the point shifted from will not be seen worse, and there will be no swing. As improvement is made, the speed can be increased. It is usually impossible, however, to realize the swing if the shifting is more rapid than two or three times a second.

1 Double and multiple vision.

Imagination Helps 165

A mental picture of a letter can, as a rule, be made to swing precisely as can a letter on the test card. Occasionally one meets a patient with whom the reverse is true; but for most patients the mental swing is easier at first than visual swinging; and when they become able to swing in this way, it becomes easier for them to swing the letters on the test card. By alternating mental with visual swinging and shifting, rapid progress is sometimes made. As relaxation becomes more perfect, the mental swing can be shortened, until it becomes possible to conceive and swing a letter the size of a period in a newspaper. This is easier, when it can be done, than swinging a larger letter, and many patients have derived great benefit from it.

All persons, no matter how great their error of refraction, when they shift and swing successfully, correct it partially or completely, as demonstrated by the retinoscope, for at least a fraction of a second. This time may be so short that the patient is not conscious of improved vision; but it is possible for him to

imagine it, and then it becomes easier to maintain the relaxation long enough to be conscious of the improved sight. For instance, the patient, after looking away from the card, may look back to the big C, and for a fraction of a second the error of refraction may be lessened or corrected, as demonstrated by the retinoscope. Yet he may not be conscious of improved vision. By imagining that the C is seen better, however, the moment of relaxation may be sufficiently prolonged to be realized.

When swinging, either mental or visual, is successful, the patient may become conscious of a feeling of relaxation which is manifested as a sensation of universal swinging. This sensation communicates itself to any

166 Shifting and Swinging

object of which the patient is conscious. The motion may be imagined in any part of the body to which the attention is directed. It may be communicated to the chair in which the patient is sitting, or to any object in the room, or elsewhere, which is remembered. The building, the city, the whole world, in fact, may appear to be swinging. When the patient becomes conscious of this universal swinging, he loses the memory of the object with which it started; but so long as he is able to maintain the movement in a direction contrary to the original movement of the eyes, or the movement imagined by the mind, relaxation is maintained. If the direction is changed, however, strain results. To imagine the universal swing with the eyes closed is easy, and some patients soon become able to do it with the eyes open. Later the feeling of relaxation which accompanies the swing may be realized without consciousness of the latter; but the swing can always be produced when the patient thinks of it.

There is but one cause of failure to produce a swing, and that is strain. Some people try to make the letters swing by effort. Such efforts always fail. The eyes and mind do not swing the letters; they swing of themselves. The eye can shift voluntarily. This is a muscular act resulting from a motor impulse. But the swing comes of its own accord when the shifting is normal. It does not produce relaxation, but is an evidence of it; and while of no value in itself is, like the period, very valuable as an indication that relaxation is being maintained.

The following methods of shifting have been found useful in various cases:

One Cause of Failure 167

No. 1 -

(a) Regard a letter.

(b) Shift to a letter on the same line far enough away so that the first is seen worse.

(c) Look back at No. 1 and see No. 2 worse.

(d) Look at the letters alternately for a few seconds, seeing worse the one not regarded.

When successful, both letters improve and appear to move from side to side in a direction opposite to the movement of the eye.

No. 2 -

(a) Look at a large letter.

(b) Look at a smaller one a long distance away from it. The large one is then seen worse.

(c) Look back and see it better.

(d) Repeat half a dozen times.

When successful, both letters improve, and the card appears to move up and down.

No. 3 -

Shifting by the above methods enables the patient to see one letter on a line better than the other letters, and, usually, to distinguish it in flashes. In order to see the letter continuously it is necessary to become able to shift from the top to the bottom, or from the bottom to the top, seeing worse the part not directly regarded, and producing the illusion of a vertical swing.

(a) Look at a point far enough above the top of the letter to see the bottom, or the whole letter worse.

(b) Look at a point far enough below the bottom to see the top, or the whole letter, worse.

(c) Repeat half a dozen times.

168 Shifting and Swinging

If successful, the letter will appear to move up and down, and the vision will improve. The shift can then be shortened until it becomes possible to shift between the top and the bottom of the letter and maintain the swing. The letter is now seen continuously. If the method fails, rest the eyes, palm, and try again.

One may also practice by shifting from one side of the letter to a point beyond the other side, or from one corner to a point beyond the other corner.

No. 4 -

(a) Regard a letter at the distance at which it is seen best. In myopia this will be at the near-point, a foot or less from the face. Shift from the top to the bottom until able to see each worse alternately, when the letter will appear blacker than before, and an illusion of swinging will be produced.

(b) Now close the eyes, and shift from the top to the bottom of the letter mentally.

(c) Regard a blank wall with the eyes open, and do the same. Compare the ability to shift and swing mentally with the ability to do the same visually at the near-point.

(d) Then regard the letter at the distance, and shift from the top to the bottom. If successful, the letter will improve, and an illusion of swinging will be produced.

No. 5 -

Some patients, particularly children, are able to see

better when one points to the letters. In other cases

Pointing to the Letters 169

this is a distraction. When the method is found successful one can proceed as follows:

(-a) Place the tip of the finger three or four inches below the letter. Let the patient regard the letter, and shift to the tip of the finger, seeing the letter worse.

(b) Reduce the distance between the finger and the letter, first to two or three inches, then to one or two, and finally to half an inch, proceeding each time as in (a).

If successful, the patient will become able to look from the top to the bottom of the letter, seeing each worse alternately, and producing the illusion of swinging. It will then be possible to see the letter continuously.

No. 6 -

When the vision is imperfect it often happens that, when the patient looks at a small letter, some of the larger letters on the upper lines, or the big C at the top, look blacker than the letter regarded. This makes it impossible to see the smaller letters perfectly. To correct this eccentric fixation regard the letter which is seen best, and shift to the smaller letter. If successful, the small letter, after a few movements, will appear blacker than the larger one. If not successful after a few trials, rest the eyes by closing and palming, and try again. One may also shift from the large letter to a point some distance below the small letter, gradually approaching the latter as the vision improves.

No. 7 -

Shifting from a card at three or five feet to one at ten or twenty feet often proves helpful, as the unconscious

170 Shifting and Swinging

memory of the letter seen at the near-point helps to bring out the one at the distance.

Different people will find these various methods of shifting more or less satisfactory. If any method does not succeed, it should be abandoned after one or two trials and something else tried. It is a mistake to continue the practice of any method which does not yield prompt results. The cause of the failure is strain, and it does no good to continue the strain.

When it is not possible to practice with the Snellen test card, other objects may be utilized. One can shift, for instance, from one window of a distant building to another, or from one part of a window to another part of the same window, from one auto to another, or from one part of an auto to another part, producing, in each case, the illusion that the objects are moving in a direction contrary to the movement of the eye. When talking to people, one can shift from one person to another, or from one part of the face to another part. When reading a book, or newspaper, one can shift consciously from one word or letter to another, or from one part of a letter to another.

Shifting and swinging, as they give the patient something definite to do, are often more successful than other methods of obtaining relaxation, and in some cases remarkable results have been obtained simply by demonstrating to the patient that staring lowers the vision and shifting improves it. One patient, a girl of sixteen with progressive myopia, obtained very prompt relief by shifting. She came to the office wearing a pair of glasses tinted a pale yellow, with shades at the sides; and in spite of this protection she was so annoyed by the light that her eyes were almost closed, and she had great

Cured by Shifting 171

difficulty in finding her way about the room. Her vision without glasses was 3/200. All reading had been forbidden, playing the piano from the notes was not allowed, and she had been obliged to give up the idea of going to college. The sensitiveness to light was relieved in a few minutes by focussing the light of the sun upon the upper part of the eyeball when she looked far down, by means of a burning glass (see Chapter XVII). The patient was then seated before a Snellen test card and directed to look away from it, rest her eyes, and then look at the big C. For a fraction of a second her vision was improved, and by frequent demonstrations she was made to realize that any effort to see the letters always lowered the vision. By alternately looking away, and then looking back at the letters for a fraction of a second, her vision improved so rapidly that in the course of half an hour it was almost normal for the distance. Then diamond type was given her to read. The attempt to read it at once brought on a severe pain. She was directed to proceed as she had in reading the Snellen test card; and in a few minutes, by alternately looking away and then looking at the first letter of each word in turn, she became able to read without fatigue, discomfort, or pain. She left the office without her glasses, and was able to see her way without difficulty. Other patients have been benefited as promptly by this simple method.

CHAPTER XVI

THE ILLUSIONS OF IMPERFECT AND OF NORMAL SIGHT

PERSONS with imperfect sight always have illusions of vision; so do persons with normal sight. But while the illusions of normal sight are an evidence of relaxation, the illusions of imperfect sight are an evidence of strain. Some persons with errors of refraction have few illusions, others have many; because the strain which causes the error of refraction is not the same strain that is responsible for the illusions.

The illusions of imperfect sight may relate to the

color, size, location and form of the objects regarded. They may include appearances of things that have no existence at all, and various other curious and interesting manifestations.

ILLUSIONS OF COLOR

When a patient regards a black letter and believes it to be grey, yellow, brown, blue, or green, he is suffering from an illusion of color. This phenomenon differs from colorblindness. The color-blind person is unable to differentiate between different colors, usually blue and green, and his inability to do so is constant. The person suffering from an illusion of color does not see the false colors constantly or uniformly. When he looks at the Snellen test card the black letters may appear to him at one time to be grey; but at another moment they may appear to be a shade of yellow, blue, or brown. Some

172

Vagaries of Color and Size 173

patients always see the black letters red; to others they appear red only occasionally. Although the letters are all of the same color, some may see the large letters black and the small ones yellow or blue. Usually the large letters are seen darker than the small ones, whatever color they appear to be. Often different colors appear in the same letter, part of it seeming to be black, perhaps, and the rest grey or some other color. Spots of black, or of color, may appear on the white; and spots of white, or of color, on the black.

ILLUSIONS OF SIZE

Large letters may appear small, or small letters large. One letter may appear to be of normal size, while another of the same size and at the same distance may appear larger or smaller than normal. Or a letter may appear to be of normal size at the near-point and at the distance, and only half that size at the middle distance. When a person can judge the size of a letter correctly at all distances up to twenty feet his vision is normal. If the size appears different to him at different distances, he is suffering from an illusion of size. At great distances the judgment of size is always imperfect, because the sight at such distances is

imperfect, even though perfect at ordinary distances. The stars appear to be dots, because the eye does not possess perfect vision for objects at such distances. A candle seen half a mile away appears smaller than at the near-point; but seen through a telescope giving perfect vision at that distance it will be the same as at the near-point. With improved vision the ability to judge size improves.

The correction of an error of refraction by glasses seldom enables the patient to judge size as correctly as

174 Illusions of Imperfect and Normal Sight

the normal eye does, and the ability to do this may differ very greatly in persons having the same error of refraction. A person with ten diopters of myopia corrected by glasses may (rarely) be able to judge the sizes of objects correctly. Another person, with the same degree of myopia and the same glasses, may see them only one-half or one-third their normal size. This indicates that errors of refraction have very little to do with incorrect perceptions of size.

ILLUSIONS OF FORM

Round letters may appear square or triangular; straight letters may appear curved; letters of regular form may appear very irregular; a round letter may appear to have a checkerboard or a cross in the center. In short, an infinite variety of changing forms may be seen. Illumination, distance and environment are all factors in this form of imperfect sight. Many persons can see the form of a letter correctly when other letters are covered, but when the other letters are visible they cannot see it. The indication of the position of a letter by a pointer helps some people to see it. Others are so disturbed by the pointer that they cannot see the letter so well.

ILLUSIONS OF NUMBER

Multiple images are frequently seen by persons with imperfect sight, either with both eyes together, with each eye separately, or with only one eye. The manner in which these multiple images make their appearance is sometimes very curious. For instance, a patient with presbyopia read the word HAS normally with both eyes. The word PHONES he read correctly with the left eye;

Strange Tricks of the Mind 175

but when he read it with the right eye he saw the letter P double, the imaginary image being a little distance to the left of the real one. The left eye, while it had normal vision for the word PHONES, multiplied the-shaft of a pin when this object was in a vertical position (the head remaining single), and multiplied the head when the position was changed to the horizontal (the shaft then remaining single). When the point of the pin was placed below a very small letter, the point was sometimes doubled while the letter remained single. No error of refraction can account for these phenomena. They are tricks of the mind only. The ways in which multiple images are arranged are endless. They are sometimes placed

vertically, sometimes horizontally or obliquely, and sometimes in circles, triangles and other geometrical forms. Their number, too, may vary from two to three, four, or more. They may be stationary, or may change their position more or less rapidly. They also show an infinite variety of color, including a white even whiter than that of the background.

ILLUSIONS OF LOCATION

A period following a letter on the same horizontal level as the bottom of the letter may appear to change its position in a great variety of curious ways. Its distance from the letter may vary. It may even appear on the other side of the letter. It may also appear above or below the line. Some persons see letters arranged in irregular order. In the case of the word AND, for instance, the D may occupy the place of the N. or the first letter may change places with the last. All these things are mental illusions. The letters sometimes ap

176 Illusions of Imperfect and Normal Sight

pear to be farther off than they really are. The small letters, twenty feet distant, may appear to be a mile away. Patients troubled by illusions of distance sometimes ask if the position of the card has not been changed.

ILLUSIONS OF NON-EXISTENT OBJECTS

When the eye has imperfect sight the mind not only distorts what the eye sees, but it imagines that it sees things that do not exist. Among illusions of this sort are the floating specks which so often appear before the eyes when the sight is imperfect, and even when it is ordinarily very good. These specks are known scientifically as "muscae volitantes," or "flying flies," and although they are of no real importance, being symptoms of nothing except mental strain, they have attracted so much attention, and usually cause so much alarm to the patient, that they will be discussed at length in another chapter.

ILLUSIONS OF COMPLEMENTARY COLORS

When the sight is imperfect the subject, on looking away from a black, white, or brightly colored object, and closing the eyes, often imagines for a few seconds that he sees the object in a complementary, or approximately complementary, color. If the object is black upon a white background, a white object upon a black background will be seen. If the object is red, it may be seen as blue; and if it is blue, it may appear to be red. These illusions, which are known as "after-images," may also be seen, though less commonly, with the eyes open, upon any background at which the subject happens to look, and are often so vivid that they appear to be real.

The Color of the Sun 177

ILLUSIONS OF THE COLOR OF THE SUN

Persons with normal sight see the sun white, the whitest white there is; but when the sight is imperfect it may appear to be any color in the spectrum - red, blue, green, purple, yellow, etc. In fact, it has even been described by persons with imperfect vision as totally black. The setting sun commonly appears to be red, because of atmospheric conditions; but in many cases these conditions are not such as to change the color, and while this still appears to be red to persons with imperfect vision, to persons with normal vision it appears to be white. When the redness of a red sun is an illusion, and not due to atmospheric conditions, its image on the ground glass of a camera will be white, not red, and the rays focussed with a burning glass will also be white. The same is true of a red moon.

BLIND SPOTS AFTER LOOKING AT THE SUN

After looking at the sun most people see black or colored spots which may last from a few minutes to a year or longer, but are never permanent. These spots are also illusions, and are not due, as is commonly supposed, to any organic change in the eye. Even the total blindness which sometimes results, temporarily, from looking at the sun, is only an illusion.

ILLUSIONS OF TWINKLING STARS

The idea that the stars should twinkle has been embodied in song and story, and is generally accepted as part of the natural order of things; but it can be demon

178 Illusions of Imperfect and Normal Sight

strated that this appearance is simply an illusion of the mind.

CAUSE OF THE ILLUSIONS OF IMPERFECT SIGHT

All the illusions of imperfect sight are the result of a strain of the mind, and when the mind is disturbed for any reason illusions of all kinds are very likely to occur. This strain is not only different from the strain that produces the error of refraction, but it can be demonstrated that for each and every one of these illusions there is a different kind of strain. Alterations of color do not necessarily affect the size or form of objects, or produce any other illusion, and it is possible to see the color of a letter, or of a part of a letter, perfectly, without recognizing the letter. To change black letters into blue, or yellow, or another color, requires a subconscious strain to remember or imagine the colors concerned, while to alter the form requires a subconscious strain to see the form in question. With a little practice anyone can learn to produce illusions of form and color by straining consciously in the same way that one strains unconsciously; and whenever illusions are produced in this way it will be found that eccentric fixation and an error of refraction have also been produced.

The strain which produces polyopia is different again from the strain which produces illusions of color,

size and form. After a few attempts most patients easily learn to produce polyopia at will. Staring or squinting, if the strain is great enough, will usually make one see double. By looking above a light, or a letter, and then trying to see it as well as when directly regarded, one can produce an illusion of several lights, or letters, arranged vertically. If the strain is great enough, there

Conscious Production of Illusions 179

may be as many as a dozen of them. By looking to the side of the light or letter, or looking away obliquely at any angle, the images can be made to arrange themselves horizontally, or obliquely at any angle.

To see objects in the wrong location, as when the first letter of a word occupies the place of the last, requires an ingenuity of eccentric fixation and an education of the imagination which is unusual.

The black or colored spots seen after looking at the sun, and the strange colors which the sun sometimes seems to assume, are also the result of the mental strain. When one becomes able to look at the orb of day without strain, these phenomena immediately disappear.

After-images have been attributed to fatigue of the retina, which is supposed to have been so overstimulated by a certain color that it can no longer perceive it, and therefore seeks relief in the hue which is complementary to this color. If it gets tired looking at the black C on the Snellen test card, for instance, it is supposed to seek relief by seeing the C white. This explanation of the phenomenon is very ingenious but scarcely plausible. The eyes cannot see when they are closed; and if they appear to see under these conditions, it is obvious that the subject is suffering from a mental illusion with which the retina has nothing to do. Neither can they see what does not exist; and if they appear to see a white C on a green wall where there is no such object, it is obvious again that the subject is suffering from a mental illusion. The after-image indicates, in fact, simply a loss of mental control, and occurs when there is an error of refraction, because this condition also is due to a loss of mental control. Anyone can produce an afterimage at will by trying to see the big C all alike - that is, under a strain;

180 Illusions of Imperfect and Normal Sight

but one can look at it indefinitely by central fixation without any such result.

While persons with imperfect sight usually see the stars twinkle, they do not necessarily do so. Therefore it is evident that the strain which causes the twinkling is different from that which causes the error of refraction. If one can look at a star without trying to see it, it does not twinkle; and when the illusion of twinkling has been produced, one can usually stop it by "swinging" the star. On the other hand, one can start the planets, or even the moon, to twinkling, if one strains sufficiently to see them.

ILLUSIONS OF NORMAL SIGHT

The illusions of normal sight include all the phenomena of central fixation. When the eye with normal sight looks at a letter on the Snellen test card, it sees the point fixed best, - and everything else in the field of vision appears less distinct. As a matter of fact, the whole letter and all the letters may be perfectly black and distinct, and the impression that one letter is blacker than the others, or that one part of a letter is blacker than the rest, is an illusion. The normal eye, however, may shift so rapidly that it appears to see a whole line of small letters all alike simultaneously. As a matter of fact there is, of course, no such picture on the retina. Each letter has not only been seen separately, but it has been demonstrated in the chapter on "Shifting and Swinging" that if the letters are seen at a distance of fifteen or twenty feet, they could not be recognized unless about four shifts were made on each letter. To produce the impression of a simultaneous picture of fourteen letters,

All Vision an Illusion 181

therefore, some sixty or seventy pictures, each with some one point more distinct than the rest, must have been produced upon the retina. The idea that the letters are seen all alike simultaneously is, therefore, an illusion. Here we have two different kinds of illusions. In the first case the impression made upon the brain is in accordance with the picture on the retina, but not in accordance with the fact. In the second the mental impression is in accordance with the fact, but not with the pictures upon the retina.

The normal eye usually sees the background of a letter whiter than it really is. In looking at the letters on the Snellen test card it sees white streaks at the margins of the letters, and in reading fine print it sees between the lines and the letters, and in the openings of the letters, a white more intense than the reality. Persons who cannot read fine print may see this illusion, but less clearly. The more clearly it is seen, the better the vision; and if it can be imagined consciously - it is imagined unconsciously when the sight is normal - the vision improves. If the lines of fine type are covered, the streaks between them disappear. When the letters are regarded through a magnifying glass by the eye with normal sight, the illusion is not destroyed, but the intensity of the white and black are lessened. With imperfect sight it may be increased to some extent by this means, but will remain less intense than the white and black seen by the normal eye. The facts demonstrate that perfect sight cannot be obtained with glasses.

The illusions of movement produced by the shifting of the eye and described in detail in the chapter on "Shifting and Swinging" must also be numbered among the illusions of normal sight, and so must the perception of

182 Illusions of Imperfect and Normal Sight

objects in an upright position. This last is the most curious illusion of all. No matter what the position of the head, and regardless of the fact that the image on the retina is inverted, we always see things right side up.

CHAPTER XVII

VISION UNDER ADVERSE CONDITIONS A BENEFIT TO THE EYES

ACCORDING to accepted ideas of ocular hygiene, it is important to protect the eyes from a great variety of influences which are often very difficult to avoid, and to which most people resign themselves with the uneasy sense that they are thereby "ruining their eyesight." Bright lights, artificial lights, dim lights, sudden fluctuations of light, fine print, reading in moving vehicles, reading lying down, etc., have long been considered "bad for the eyes," and libraries of literature have been produced about their supposedly direful effects. These ideas are diametrically opposed to the truth. When the eyes are properly used, vision under adverse conditions not only does not injure them, but is an actual benefit, because a greater degree of relaxation is required to see under such conditions than under more favorable ones. It is true that the conditions in question may at first cause discomfort, even to persons with normal vision; but a careful study of the facts has demonstrated that only persons with imperfect sight suffer seriously from them, and that such persons, if they practice central fixation, quickly become accustomed to them and derive great benefit from them.

Although the eyes were made to react to the light, a very general fear of the effect of this element upon the organs of vision is entertained both by the medical profession and by the laity. Extraordinary precautions are 183

184 Adverse Conditions a Benefit to the Eyes

taken in our homes, offices and schools to temper the light, whether natural or artificial, and to insure that it shall not shine directly into the eyes; smoked and amber glasses, eye-shades, broad-brimmed hats and parasols are commonly used to protect the organs of vision from what is considered an excess of light; and when actual disease is present, it is no uncommon thing for patients to be kept for weeks, months and years in dark rooms, or with bandages over their eyes.

[[NOTE](#)]

It is not light but darkness that is dangerous to the eye. Prolonged exclusion from the light always lowers the vision, and may produce serious inflammatory conditions. Among young children living in tenements this is a somewhat frequent cause of ulcers upon the cornea, which ultimately destroy the sight. The children, finding their eyes sensitive to light, bury them in the pillows

190 Adverse Conditions a Benefit to the Eyes

and thus shut out the light entirely. The universal fear of reading or doing fine work in a dim light is, however, unfounded. So long as the light is sufficient so that one can see without discomfort, this

practice is not only harmless, but may be beneficial.

Sudden contrasts of light are supposed to be particularly harmful to the eye. The theory on which this idea is based is summed up as follows by Fletcher B. Dresslar, specialist in school hygiene and sanitation of the United States Bureau of Education:

"The muscles of the iris are automatic in their movements, but rather slow. Sudden contrasts of strong light and weak illumination are painful and likewise harmful to the retina. For example, if the eye, adjusted to a dim light, is suddenly turned toward a brilliantly lighted object, the retina will receive too much light and will be shocked before the muscles controlling the iris can react to shut out the superabundance of light. If contrasts are not strong, but frequently made, that is, if the eye is called upon to function where frequent adjustments in this way are necessary, the muscles controlling the iris become fatigued, respond more slowly and less perfectly. As a result, eyestrain in the ciliary muscles is produced and the retina is over-stimulated. This is one cause of headaches and tired eyes." ¹

¹ School Hygiene, Brief Course Series in Education, edited by Monroe, 1916, p. 240

192 Adverse Conditions a Benefit to the Eyes

There is no evidence whatever to support these statements. Sudden fluctuations of light undoubtedly cause discomfort to many persons, but, far from being injurious, I have found them, in all cases observed, to be actually beneficial. The pupil of the normal eye, when it has normal sight, does not change appreciably under the influence of changes of illumination; and persons with normal vision are not inconvenienced by such changes. I have seen a patient look directly at the sun after coming from an imperfectly lighted room, and then, returning to the room, immediately pick up a newspaper and read it. When the eye has imperfect sight, the pupil usually contracts in the light and expands in the dark, but it has been observed to contract to the size of a pinhole in the dark. Whether the contraction takes place under the influence of light or of darkness, the cause is the same, namely, strain. Persons with imperfect sight suffer great inconvenience, resulting in lowered vision, from changes in the intensity of the light; but the lowered vision is always temporary, and if the eye is persistently exposed to these conditions, the sight is benefited. Such practices as reading alternately in a bright and a dim light, or going from a dark room to a well-lighted one, and vice versa, are to be recommended. Even such rapid and violent fluctuations of light as those involved in the production of the moving picture are, in the long run, beneficial to all eyes. I always advise patients under treatment for the cure of defective vision to go to the movies frequently and practice central fixation. They soon become accustomed to the flickering light, and afterward other light and reflections cause less annoyance.

Reading is supposed to be one of the necessary evils of civilization; but it is believed that by avoiding fine print, and taking care to read only under certain favorable conditions, its deleterious influences can be minimized. Extensive investigations as to the effect of various styles of print on the eyesight of school children have been made, and detailed rules have been laid down as to the size of the print, its shading, the distance of

Supposed Dangers of Reading 193

the letters from each other, the spaces between the lines, the length of the lines, etc.. As regards the effects of different sorts of type on the human eye in general and those of children in particular, Dr. A. G. Young, in his much quoted report¹ to the Maine State Board of Health makes the following interesting observations:

Pearl, as the printers call it, is unfit for any eyes, yet the piles of Bibles and Testaments annually printed in it tempt many eyes to self-destruction.

Agate is the type in which a boy, to the writer's knowledge, undertook to read the Bible through, His outraged eyes broke down with asthenopia before he went far and could be used but little for school work the next two years.

Nonpareil is used in some papers and magazines for children, but, to spare the eyes, all such should, and do, go on the list of forbidden reading matter in those homes where the danger of such print is understood.

Minion is read by the healthy, normal young eye without appreciable difficulty, but even to the sound eye the danger of strain is so great that all books and magazines for children printed from it should be banished from the home and school.

Brevier is much used in newspapers, but is too small for magazines or books for young folks.

Bourgeois is much used in magazines, but should be used in only those school books to which a brief reference is made.

Long Primer is suitable for school readers for the higher and intermediate grades, and for text books generally.

Small Pica is still a more luxurious type, used in the North American Review and the Forum.

Pica is a good type for books for small children.

Great Primer should be used for the first reading book.

1 Seventh Annual Report to the Maine State Board of Health, by the secretary, Dr. A. G. Young, 1891, p. 193.

194 Adverse Conditions a Benefit to the Eyes

All this is directly contrary to my own experience. Children might be bored by books in excessively small print; but I have never seen any reason for supposing that their eyes, or any other eyes, would be harmed by such type. On the contrary, the reading of fine print, when it can be done without discomfort, has invariably proven to be beneficial, and the dimmer the light in which it can be read, and the closer to the eyes it can be held, the greater the benefit. By this means severe pain in the eyes has been relieved in a few minutes or even instantly. The reason is that fine print cannot be read in a dim light and close to the eyes unless the eyes are relaxed, whereas large print can be read in a good light and at ordinary reading distance although the eyes may be under a strain. When fine print can be read under adverse conditions, the reading of ordinary print under ordinary conditions is vastly improved. In myopia it may be a benefit to strain to see fine print, because myopia is always lessened when there is a strain to see near objects, and this has sometimes counteracted the tendency to strain in looking at distant objects, which is always associated with the production of myopia. Even straining to see print so fine that it cannot be read is a benefit to some myopes.

Persons who wish to preserve their eyesight are frequently warned not to read in moving vehicles; but since under modern conditions of life many persons have to spend a large part of their time in moving vehicles, and many of them have no other time to read, it is useless to expect that they will ever discontinue the practice. Fortunately the theory of its injuriousness is not borne out by the facts. When the object regarded is moved more or less rapidly, strain and lowered vision are, at

Benefits of Reading Fine Print 195

Seven Truths of Normal Sight

- 1 - Normal Sight can always be demonstrated in the normal eye, but only under favorable conditions.
- 2 - Central Fixation: The letter or part of the letter regarded is always seen best.
- 3 - Shifting: The point regarded changes rapidly and continuously.
- 4 - Swinging: When the shifting is slow, the letters appear to move from side to side or in other directions with a pendulum-like motion.
- 5 - Memory is perfect The color and background of the letters, or other objects seen are remembered

perfectly, instantaneously and continuously

6 - Imagination is good. One may even see the white part of the letters whiter than it really is, while the black is not altered by distance, illumination, size, or form, of the letters.

7 - Rest or relaxation of the eye and mind is perfect and can always be demonstrated.

When one of these seven fundamentals is perfect all are perfect.

Fig. 49. Specimen of Diamond Type

Many patients have been greatly benefited by reading type of this size.

Fig. 50. Photographic Type Reduction

Patients who can read photographic type reductions are instantly relieved of pain and discomfort when they do so and those who cannot read such type may be benefited simply by looking at it.

196 Adverse Conditions a Benefit to the Eyes

first, always produced; but this is always temporary, and ultimately the vision is improved by the practice.

There is probably no visual habit against which we have been more persistently warned than that of reading in a recumbent posture. Many plausible reasons have been adduced for its supposed injuriousness; but so delightful is the practice that few, probably, have ever been deterred from it by fear of the consequences. It is gratifying to be able to state, therefore, that I have found these consequences to be beneficial rather than injurious. As in the case of the use of the eyes under other difficult conditions, it is a good thing to be able to read lying down, and the ability to do it improves with practice. In an upright position, with a good light coming over the left shoulder, one can read with the eyes under a considerable degree of strain; but in a recumbent posture, with the light and the angle of the page to the eye unfavorable, one cannot read unless one relaxes. Anyone who can read lying down without discomfort is not likely to have any difficulty in reading under ordinary conditions.

The fact is that vision under difficult conditions is good mental training. The mind may be disturbed at first by the unfavorable environment; but after it has become accustomed to such environments, the mental control, and, consequently, the eyesight are improved. To advise against using the eyes under unfavorable conditions is like telling a person who has been in bed for a few weeks and finds it difficult to walk to refrain from such exercise. Of course, discretion must be used in both cases. [[NOTE](#)]

Discretion Must be Used 197

But just as the invalid may gradually increase his strength until the Marathon has no terrors for him, so may the eye with defective sight be educated until all the rules with which we have so long allowed ourselves to be harassed in the name of "eye hygiene" may be disregarded, not only with safety but with benefit.

Note from the Webmaster: The Webmaster (Alex Eulenberg) believes that some passages from the original version of this chapter are so dangerously false or misleading that he has not included them in this edition, with or without a disclaimer. In this chapter, Bates describes the effects of looking directly at the sun as "always temporary" and "mental illusions." No. If you look at the sun too long and too hard you can damage your retina and cause permanent blind spots. This permanent condition is called solar retinopathy and is distinct from the well-known temporary "snow blindness."

CHAPTER XVIII

OPTIMUMS AND PESSIMUMS

IN nearly all cases of imperfect sight due to errors of refraction there is some object, or objects, which can be regarded with normal vision. Such objects I have called "optimums." On the other hand, there are some objects which persons with normal eyes and ordinarily normal sight always see imperfectly, an error of refraction being produced when they are regarded, as demonstrated by the retinoscope. Such objects I have called "pessimums." An object becomes an optimum, or a pessimum, according to the effect it produces upon the mind, and in some cases this effect is easily accounted for.

For many children their mother's face is an optimum, and the face of a stranger a pessimum. A dressmaker was always able to thread a No. 10 needle with a fine thread of silk without glasses, although she had to put on glasses to sew on buttons, because she could not see the holes. She was a teacher of dressmaking, and thought the children stupid because they could not tell the difference between two different shades of black. She could match colors without comparing the samples. Yet she could not see a black line in a photographic copy of the Bible which was no finer than a thread of silk, and she could not remember a black period. An employee in a cooperage factory, who had been engaged for years in picking out defective barrels as they went rapidly past him on an inclined plane, was able to continue his work

198

Idiosyncrasies of the Mind 199

after his sight for most other objects had become very defective, while persons with much better sight for the Snellen test card were unable to detect the defective barrels. The familiarity of these various objects made it possible for the subjects to look at them without strain - that is, without trying to see them. Therefore the barrels were to the cooper optimums; while the needle's eye and the colors of silk and fabrics were optimums to the dressmaker. Unfamiliar objects, on the contrary, are always pessimums, as pointed out in the chapter on "The Variability of the Refraction of the Eye."

In other cases there is no accounting for the idiosyncrasy of the mind which makes one object a pessimum and another an optimum. It is also impossible to account for the fact that an object may be an optimum for one eye and not for the other, or an optimum at one time and at one distance and not at others. Among these unaccountable optimums one often finds a particular letter on the Snellen test card. One patient, for instance, was able to see the letter K on the forty, fifteen and ten lines, but could see none of the other letters on these lines, although most patients would see some of them, on account of the simplicity of their outlines, better than they would such a letter as K.

Pessimums may be as curious and unaccountable as optimums. The letter V is 50 simple in its outlines that many people can see it when they cannot see others on the same line. Yet some people are unable to

distinguish it at any distance, although able to read other letters in the same word, or on the same line of the Snellen test card. Some people again will not only be unable to recognize the letter V in a word, but also to read any word that contains it, the pessimum lowering their sight not

200 Optimums and Pessimums

only for itself but for other objects. Some letters, or objects, become pessimums only in particular situations. A letter, for instance, may be a pessimum when located at the end or at the beginning of a line or sentence, and not in other places. When the attention of the patient is called to the fact that a letter seen in one location ought logically to be seen equally well in others, the letter often ceases to be a pessimum in any situation.

A pessimum, like an optimum, may be lost and later become manifest. It may vary according to the light and distance. An object which is a pessimum in a moderate light may not be so when the light is increased or diminished. A pessimum at twenty feet may not be one at two feet, or thirty feet, and an object which is a pessimum when directly regarded may be seen with normal vision in the eccentric field.

For most people the Snellen test card is a pessimum. If you can see the Snellen test card with normal vision, you can see almost anything else in the world. Patients who cannot see the letters on the Snellen test card can often see other objects of the same size and at the same distance with normal sight. When letters which are seen imperfectly, or even letters which cannot be seen at all, or which the patient is not conscious of seeing are regarded, the error of refraction is increased. The patient may regard a blank white card without any error of refraction; but if he regards the lower part of a Snellen test card, which appears to him to be just as blank as the blank card, an error of refraction can always be demonstrated, and if the visible letters of the card are covered, the result is the same. The pessimum may, in short, be letters or objects which the patient is not conscious of seeing. This phenomenon is very common. When the

How Pessimums Become Optimums 201

card is seen in the eccentric field it may have the effect of lowering the vision for the point directly regarded. For instance, a patient may regard an area of green wallpaper at the distance, and see the color as well as at the near-point; but if a Snellen test card on which the letters are either seen imperfectly, or not seen at all, is placed in the neighborhood of the area being regarded, the retinoscope may indicate an error of refraction. When the vision improves the number of letters on the card which are pessimums diminishes and the number of optimums increases, until the whole card becomes an optimum.

A pessimum, like an optimum, is a manifestation of the mind. It is something associated with a strain to

see, just as an optimum is something which has no such association. It is not caused by the error of refraction, but always produces an error of refraction; and when the strain has been relieved it ceases to be a pessimum and becomes an optimum.

CHAPTER XIX

THE RELIEF OF PAIN AND OTHER SYMPTOMS

BY THE AID OF THE MEMORY

MANY years ago patients who had been cured of imperfect sight by treatment without glasses quite often told me that after their vision had become perfect they were always relieved of pain, not only in the eyes and head, but in other parts of the body, even when the pain was apparently caused by some organic disease, or by an injury. The relief in many cases was so striking that I investigated some thousands of cases and found it to be a fact that persons with perfect sight, or the memory of perfect sight - that is, of something perfectly seen - do not suffer pain in any part of the body, while by a strain or effort to see I have produced pain in various parts of the body.

By perfect sight is not meant, necessarily, the perfect visual perception of words, letters, or objects, of a more or less complicated form. To see perfectly the color alone is sufficient, and the easiest color to see perfectly is black. But perfect sight is never continuous, careful scientific tests having shown that it is seldom maintained for more than a few minutes and usually not so long. For practical purposes in the relief of pain, therefore, the memory is more satisfactory than sight.

When black is remembered perfectly a temporary, if not a permanent, relief of pain always results. The skin may be pricked with a sharp instrument without causing discomfort. The lobe of the ear may be pinched be

Pain of Operation Prevented 203

tween the nails of the thumb and first finger, and no pain will be felt. At the same time the sense of touch becomes more acute. The senses of taste, smell and hearing are also improved, while the efficiency of the mind is increased. The ability to distinguish different temperatures is increased, but one does not suffer from heat or cold. Organic conditions may not be changed; but all of the functional symptoms, such as fever, weakness, and shock, which these conditions cause, are relieved. Patients who have learned to remember black under all circumstances no longer dread to visit the dentist. When they remember a period the drill causes them no pain, and they are not annoyed even by the extraction of teeth. It is possible to perform surgical operations without anaesthetics when the patient is able to remember black perfectly. The following are only a few of many equally striking cases which might be given of the relief or prevention of pain by this means:

A patient suffered from ulceration of the eyeball, occurring at different times and resulting in the formation of holes through which the fluids in the interior escaped. These openings had to be closed by surgical operations. At first these operations were performed under the influence of cocaine; but the progressive disease of the eye caused so much congestion that complete anaesthesia was no longer attainable by the use of this drug, and ether and chloroform were employed. As so many operations were needed, it became desirable to get along, if possible, without anaesthetics, and the patient's success in relieving pain by the memory of black suggested that she might also be able to prevent the pain of operations in the same way. Her ability to do this was tested by touching her eyeball lightly with a blunt probe. At first she forgot the

204 *The Relief of Pain*

black as soon as the probe touched her eye, but later she became able to remember it. The operation was then successfully performed; the patient not only felt no pain,

Fig. 51. Operating Without Anaesthetics

The patient suffered from ulceration of the eyeball resulting in the formation of holes through which the fluids of the interior escaped. These holes had to be closed by surgical operations, and fourteen of these operations were performed without anaesthetics, because the patient was able to prevent pain by the memory of a black period.

but her self-control was better than when cocaine had been used. Later fourteen more operations were performed under the same conditions, the patient not only

No Pain in Dentist's Chair 205

suffering no pain, but, what was more remarkable, feeling no pain or soreness afterward. The patient stated that if she had been operated upon by a stranger she would probably have been so nervous that she would not

have been able to remember the black; but later she was treated by a strange dentist, who made two extractions and did some other work, all without causing her any discomfort, because she was able to remember the period perfectly.

A man who had been extremely nervous in the dentist's chair, and had had four extractions made under gas, surprised his dentist, after having learned the effect of the memory of a period in-relieving pain, by having a tooth extracted without cocaine, gas, or chloroform. The dentist complimented him on his nerve and looked incredulous when the patient said he had felt no pain at all. In a second case, that of a woman, the dentist removed the nerve from three teeth without causing the patient any pain.

A boy of fourteen came to the eye clinic of the Harlem Hospital, New York, with a foreign body deeply embedded in his cornea. It caused him much pain, and his mother stated that a number of physicians had been unable to remove it, because the child was so nervous that he could not keep still long enough, although cocaine had been used quite freely. The boy was told to look at a black object, close and cover his eyes, and think of the black object until he saw black. He was soon able to do this, and the pain in his eye was relieved. He was next taught to remember the black with his eyes open. The foreign body was then removed from the cornea. The operation was one of much difficulty and required considerable time, but the boy felt no pain. While it was

206 The Relief of Pain

in progress he was asked if he was still remembering black.

"You bet I am," he replied.

In the same hospital a surgeon from the accident ward visited the eye clinic with a friend suffering from pain in his eyes and head. The patient was benefited very quickly by relaxation methods. The surgeon said it was unusual, and spoke slightly of my methods. I challenged him to bring me a patient with pain that I could not relieve in five minutes.

"All right," he said. "I want you to understand that I am from Missouri."

He returned soon with a woman who had been suffering from severe pains in her head for several years. She had been operated upon a number of times, and had been under the care of the hospital for many months.

"You cannot help the pain in this patient's head," said the surgeon, "because she has a brain tumor."

I doubted the existence of a brain tumor, but I said: "Brain tumor or no brain tumor, my assistant will stop the pain in five minutes."

He took out his watch, opened it, looked at the time, and told my assistant to go ahead. The patient was directed to look at a large black letter, note its blackness, then to cover her closed eyes with the palms of her hands, shutting out all the light, and to remember the blackness of the letter until she saw everything black. In

less than three minutes she said:

"I now see everything perfectly black. I feel no pain in my head. I am completely relieved, and I thank you very much."

The surgeon looked bewildered, and left the room without a word.

Fig.

52. Neuralgia Relieved by Palming and the Memory of Black

While the visitor was explaining to her sceptical hostess the method of relieving pain by palming and the memory of black another member of the family, who was suffering from trigeminal neuralgia, came in, and having heard what was being said, immediately put it into practice and was cured. The hostess later developed severe pain in her head and eyes, and did not obtain any relief until she also practiced palming and the memory of black.

208 The Relief of Pain

To prevent a relapse the patient was advised to palm six times a day or oftener. The pain did not return, and she came to the clinic some weeks later to express her gratitude.

Not only does the memory of perfect sight relieve pain and the symptoms of disease, but in some cases it produces manifest relief of the causes of these symptoms. Coughs, colds, hay fever, rheumatism and glaucoma are among the conditions that have been relieved in this way.

A patient under treatment for imperfect sight from a high degree of mixed astigmatism one day came to the office with a severe cold. She coughed continually, and there was a profuse discharge from both eyes and nose. There was some fever, with a severe pain in the eyes and head, and the patient was unable to breathe through her nose because of the inflammatory swelling. Palming was successful in half an hour, when the pain and discharge ceased, the nose opened, and the breathing and temperature became normal. The benefit was permanent - a very unusual thing after one treatment.

A boy of four with whooping-cough was always relieved by covering his eyes and remembering black. The relapses became less frequent, and in a few weeks he had completely recovered.

A man who suffered every summer from attacks of hay fever, beginning in June and lasting throughout the season, was completely relieved by palming for half an hour; and after three years there had been no relapse.

A man of sixty-five who had been under treatment for rheumatism for six months without improvement obtained temporary relief by palming, and by the time his vision had become normal the relief of the rheumatism was complete.

The Power of Thought 209

In many cases of glaucoma not only the pain, but the tension which is often associated with the pain, has been completely relieved by palming. In some cases permanent relief of the tension has followed one treatment. In others many treatments have been required.

Why the memory of black should have this effect cannot be fully explained, just as the action of many drugs cannot be explained; but it is evident that the body must be less susceptible to disturbances of all kinds when the mind is under control, and only when the mind is under control can black be remembered perfectly. That pain can be produced in any part of the body by the action of the mind is not a new observation; and if the mind can produce pain, it is not surprising that it should also be able to relieve pain and the conditions which produce it. This, doubtless, is the explanation of some of the remarkable cures reported by Faith Curists and Christian Scientists. Whatever the explanation, however, the facts have been attested by numerous proofs, and are of the greatest practical value.

With a little training anyone with good sight can be taught to remember black perfectly with the eyes closed and covered, and with a little more training anyone can learn to do it with the eyes open. When one is suffering extreme pain, however, the control of the memory may be difficult, and the assistance of someone who understands the method may be necessary. With such assistance it is seldom or never impossible.

CHAPTER XX

PRESBYOPIA: ITS CAUSE AND CURE

AMONG people living under civilized conditions the accommodative power of the eye gradually declines, in most cases, until at the age of sixty or seventy it appears to have been entirely lost, the subject being absolutely dependent upon his glasses for vision at the near-point. As to whether the same thing happens among primitive people or people living under primitive conditions, very little information is available. Donders¹ says that the power of accommodation diminishes little, if at all, more rapidly among people who use their eyes much at the near-point than among agriculturists, sailors and others who use them mainly for distant vision; and Roosa and others² say the contrary. This is a fact however, that people who cannot read, no matter what their age, will manifest a failure of near vision if asked to look at printed characters, although their sight for familiar objects at the near-point may be perfect. The fact that such persons, at the age of forty-five or fifty, cannot differentiate between printed characters is no warrant, therefore, for the conclusion that their accommodative powers are declining. A young illiterate would do no better, and a young student who can read Roman characters at the near-point without difficulty always develops symptoms of imperfect sight when he attempts to read, for the first time, old English, Greek, or Chinese characters.

1 On the Anomalies of Accommodation and Refraction of the Eye, p. 223.

2 Roosa: A Clinical Manual of Diseases of the Eye, 1894, p. 537; Oliver: System of Diseases of the Eye, vol. iv, p, 431.

210

Generally Accepted as Normal 211

When the accommodative power has declined to the point at which reading and writing become difficult the patient is said to have "presbyopia," or, more popularly, "old sight"; and the condition is generally accepted, both by the popular and the scientific mind, as one of the unavoidable inconveniences of old age. "Presbyopia," says Donders, "is the normal quality of the normal, emmetropic eye in advanced age,"¹ and similar statements might be multiplied endlessly. De Schweinitz calls the condition "a normal result of growing old";² according to Fuchs it is "a physiological process which every eye undergoes";³ while Roosa speaks of the change as one which "ultimately affects every eye."⁴

The decline of accommodative power with advancing years is commonly attributed to the hardening of the lens, an influence which is believed to be augmented, in later years, by a flattening of this body and a lowering of its refractive index, together with weakness or atrophy of the ciliary muscle; and so regular is the decline, in most cases, that tables have been compiled showing the near-point to be expected at

various ages. From these it is said one might almost fit glasses without testing the vision of the subject; or, conversely, one might, from a man's glasses, judge his age within a year or two. The following table is quoted from Jackson's chapter on "The Dioptrics of the Eye," in Norris and Oliver's "System of Diseases of the Eye," 5 and does not differ materially from the tables given by Fuchs, Donders and Duane. The first

According to these depressing figures one must expect at thirty to have lost no less than half of one's original accommodative power, while at forty two-thirds of it would be gone, and at sixty it would be practically nonexistent.¹

There are many people, however, who do not fit this schedule. Many persons at forty can read fine print at four inches, although they ought, according to the table, to have lost that power shortly after twenty. Worse still, there are people who refuse to become presbyopic at all. Oliver Wendell Holmes mentions one of these cases in "The Autocrat of the Breakfast Table."

¹ An eye which, when it is at rest, focusses parallel rays upon the retina, is said to be emmetropic or normal.

The Dead Hand of German Science 213

"There is now living in New York State," he says, "an old gentleman who, perceiving his sight to fail, immediately took to exercising it on the finest print, and in this way fairly bullied Nature out of her foolish habit of taking liberties at five-and-forty, or thereabout. And now this old gentleman performs the most extraordinary feats with his pen, showing that his eyes must be a pair of microscopes. I should be afraid to say how much he writes in the compass of a half-dime - whether the Psalms or the Gospels, or the Psalms and the Gospels, I won't be positive."¹

There are also people who regain their near vision after having lost it for ten, fifteen, or more years; and there are people who, while presbyopic for some objects, have perfect sight for others. Many dressmakers, for instance, can thread a needle with the naked eye, and with the retinoscope it can be demonstrated that they accurately focus their eyes upon such objects; and yet they cannot read or write without glasses.

So far as I am aware no one but myself has ever observed the last-mentioned class of cases, but the others are known to every ophthalmologist of any experience. One hears of them at the meetings of ophthalmological societies; they are even reported in the medical journals; but such is the force of authority that when it comes to writing books they are either ignored or explained away, and every new

treatise that comes from the press repeats the old superstition that presbyopia is "a normal result of growing old." We have beaten Germany; but the dead hand of German science still oppresses our intellects and prevents us from crediting the plainest evidence of our senses. Some of us are so filled with repugnance for

1 Everyman's Library, 1908, pp. 166-167.

214 Presbyopia: Its Cause And Cure

the Hun that we can no longer endure the music of Bach, or the language of Goethe and Schiller; but German ophthalmology is still sacred, and no facts are allowed to cast discredit upon it.

Fortunately for those who feel called upon to defend the old theories, myopia postpones the advent of presbyopia. and a decrease in the size of the pupil, which often takes place in old age, has some effect in facilitating vision at the near-point. Reported cases of persons reading without glasses when over fifty or fifty-five years of age, therefore, can be easily disposed of by assuming that the subjects must be myopic, or that their pupils are unusually small. If the case comes under actual observation, the matter may not be so simple, because it may be found that the patient, so far from being myopic, is hypermetropic, or emmetropic, and that the pupil is of normal size. There is nothing to do with these cases but to ignore them. Abnormal changes in the form of the lens have also been held responsible for the retention of near vision beyond the prescribed age, or for its restoration after it has been lost, the swelling of the lens in incipient cataract affording a very convenient and plausible explanation for the latter class of cases. In cases of premature presbyopia "accelerated sclerosis" 1 Of the lens and weakness of the ciliary muscle have been assumed; and if such cases as the dressmakers who can thread their needles when they can no longer read the newspapers had been observed, no doubt some explanation consistent with the German viewpoint would have been found for them.

The truth about presbyopia is that it is not "a normal result of growing old," being both preventable and cu

I Fuchs: Text-book of Ophthalmology, p. S05.

A Form Of Hypermetropia 215

nable. It is not caused by hardening of the lens, but by a strain to see at the near-point. It has no necessary connection with age, since it occurs, in some cases, as early as ten years, while in others it never occurs at all, although the subject may live far into the so-called presbyopic age. It is true that the lens does harden with advancing years, just as the bones harden and the structure of the skin changes; but since the lens is not a factor in accommodation, this fact is immaterial, and while in some cases the lens may become flatter, or lose some of its refractive power with advancing years, it has been observed to remain

perfectly clear and unchanged in shape up to the age of ninety. Since the ciliary muscle is also not a factor in accommodation, its weakness or atrophy can contribute nothing to the decline of accommodative power. Presbyopia is, in fact, simply a form of hypermetropia in which the vision for the near-point is chiefly affected, although the vision for the distance, contrary to what is generally believed, is always lowered also. The difference between the two conditions is not always clear. A person with hypermetropia may or may not read fine print, and a person at the presbyopic age may read it without apparent inconvenience and yet have imperfect sight for the distance. In both conditions the sight at both points is lowered, although the patient may not be aware of it.

It has been shown that when the eyes strain to see at the near-point the focus is always pushed farther away than it was before, in one or all meridians; and by means of simultaneous retinoscopy it can always be demonstrated that when a person with presbyopia tries to read fine print and fails, the focus is always pushed farther away than it was before the attempt was made, indicat

216 Presbyopia: Its Cause And Cure

ing that the failure was caused by strain. Even the thought of making such an effort will produce strain, so that the refraction may be changed, and pain, discomfort and fatigue produced, before the fine print is regarded. Furthermore, when a person

with presbyopia rests the eyes by closing them, or palming, he always becomes able, for a few moments at least, to read fine print at six inches, again indicating that his previous failure was due, not to any fault of the eyes, but to a strain to see. When the strain is permanently relieved the presbyopia is permanently cured, and this has happened, not in a few cases, but in many, and at all ages, up to sixty, seventy and eighty.

The first patient that I cured of presbyopia was myself. Having demonstrated by means of experiments on the eyes of animals that the lens is not a factor in accommodation, I knew that presbyopia must be curable, and I realized that I could not look for any very general acceptance of the revolutionary conclusions I had reached so long as I wore glasses myself for a condition supposed to be due to the loss of the accommodative power of the lens. I was then suffering from the maximum degree of presbyopia. I had no accommodative power whatever, and had to have quite an outfit of glasses, because with a glass, for instance, which enabled me to read fine print at thirteen inches, I could not read it either at twelve inches or at fourteen. The retinoscope showed that when I tried to see anything at the near-point without glasses my eyes were focussed for the distance, and when I tried to see anything at the distance they were focussed for the near-point. My problem, then, was to find some way of reversing this condition and inducing my eyes to focus for the point I wished to see at the moment that I wished

Only One Man Who Could Cure Me 217

to see it. I consulted various eye specialists, but my language was to them like that of St. Paul to the Greeks, namely, foolishness. "Your lens is as hard as a stone," they said. "No one can do anything for you." Then I went to a nerve specialist. He used the retinoscope on me, and confirmed my own observations as to the peculiar contrariness of my accommodation; but he had no idea what I could do about it. He would consult some of his colleagues, he said, and asked me to come back in a month, which I did. Then he told me he had come to the conclusion that there was only one man who could cure me, and that was Dr. William H. Bates of New York.

"Why do you say that?" I asked.

"Because you are the only man who seems to know anything about it," he answered.

Thus thrown upon my own resources, I was fortunate enough to find a non-medical gentleman who was willing to do what he could to assist me, the Rev. R. B. B. Foote, of Brooklyn. He kindly used the retinoscope through many long and tedious hours while I studied my own case, and tried to find some way of accommodating when I wanted to read, instead of when I wanted to see something at the distance. One day, while looking at a picture of the Rock of Gibraltar which hung on the wall, I noted some black spots on its face. I imagined that these spots were the openings of caves, and that there were people in these caves moving about. When I did this my eyes were focussed for the reading distance. Then I looked at the same picture at the reading distance, still imagining that the spots were caves with people in them. The retinoscope showed that I had accommodated, and I was able to read the lettering beside the picture. I had,

218 Presbyopia: Its Cause And Cure

in fact, been temporarily cured by the use of my imagination. Later I found that when I imagined the letters black I was able to see them black, and when I saw them black I was able to distinguish their form. My progress after this was not what could be called rapid. It was six months before I could read the newspapers with any kind of comfort, and a year before I obtained my present accommodative range of fourteen inches, from four inches to eighteen; but the experience was extremely valuable, for I had in pronounced form every symptom subsequently observed in other presbyopic patients.

Fortunately for the patients, it has seldom taken me as long to cure other people as it did to cure myself. In some cases a complete and permanent cure was effected in a few minutes. Why, I do not know. I will never be satisfied till I find out. A patient who had worn glasses for presbyopia for about twenty years was cured in less than fifteen minutes by the use of his imagination.

When asked to read diamond type, he said he could not do so, because the letters were grey and looked all alike. I reminded him that the type was printer's ink and that there was nothing blacker than printer's ink. I asked him if he had ever seen printer's ink. He replied that he had. Did he remember how black it was? Yes. Did he believe that these letters were as black as the ink he remembered? He did, and then he read the letters; and because the improvement **in his** vision was permanent, he said that I had hypnotized

him.

In another case a presbyope of ten years' standing was cured just as quickly by the same method. When reminded that the letters which he could not read were black, he replied that he knew they were black, but that they looked grey.

Responsible For Much Defective Eyesight 219

"If you know they are black, and yet see them grey," I said, "you must imagine them grey. Suppose you imagine that they are black. Can you do that?"

"Yes," he said, "I can imagine that they are black"; and then he proceeded to read them.

These extremely quick cures are rare. In nine cases out of ten progress has been much slower, and it has been necessary to resort to all the methods of obtaining relaxation found useful in the treatment of other errors of refraction. In the more difficult cases of presbyopia the patients often suffer from the same illusions of color, size, form and number, when they try to read fine print, as do patients with hypermetropia, astigmatism, and myopia when they try to read the letters on the Snellen test card at the distance. They are unable to remember or imagine, when trying to see at the near-point, even such a simple thing as a small black spot, but can remember it perfectly when they do not try to see. Their sight for the distance is often very imperfect and always below normal, although they may have thought it perfect; and just as in the case of other errors of refraction, improvement of the distant vision improves the vision at the near-point. Regardless, however, of the difficulty of the case and the age of the patient; some improvement has always been obtained, and if the treatment was continued long enough, the patient has been cured.

The idea that presbyopia is "a normal result of growing old" is responsible for much defective eyesight. When people who have reached the presbyopic age experience difficulty in reading, they are very likely to resort at once to glasses, either with or without professional advice. In some cases such persons may be actually presbyopic; in others the difficulty may be something tempo

220 Presbyopia: Its Cause And Cure

rary, which they would have thought little about if they had been younger, and which would have passed away if Nature had been left to herself. But once the glasses are adopted, in the great majority of cases, they produce the condition they were designed to relieve, or, if it already existed, they make it worse, sometimes very rapidly, as every ophthalmologist knows. In a couple of weeks sometimes, the patient finds, as noted in the chapter on *What Glasses Do to Us*, that the large print which he could read without difficulty before

he got his glasses, can no longer be read without their aid. In from five to ten years the accommodative power of the **eye** is usually gone; and if from this point the patient does not go on to cataract, glaucoma,

or inflammation of the retina, he may consider himself fortunate. Only occasionally do the eyes refuse to submit to the artificial conditions imposed upon them; but in such cases they may keep up an astonishing struggle against them for long periods. A woman of seventy, who had worn glasses for twenty years, was still able to read diamond type and had good vision for the distance without them. She said the glasses tired her eyes and blurred her vision, but that she had persisted in wearing them, in spite of a continual temptation to throw them off, because she had been told that it was necessary for her to do so.

If persons who find themselves getting presbyopic, or who have arrived at the presbyopic age, would, instead of resorting to glasses, follow the example of the gentleman mentioned by Dr. Holmes, and make a practice of reading the finest print they can find, the idea that the decline of accommodative power is "a normal result of growing old" would soon die a natural death.

CHAPTER XXI

SQUINT AND AMBLYOPIA: THEIR CAUSE

SINCE we have two eyes, it is obvious that in the act of sight two pictures must be formed; and in order that these two-pictures shall be fused into one by the mind, it is necessary that there shall be perfect harmony of action between the two organs of vision. In looking at a distant object the two visual axes must be parallel, and in looking at an object at a less distance than infinity, which for practical purposes is less than twenty feet, they must converge to exactly the same degree. The absence of this harmony of action is known as *squint*, or *strabismus* and is one of the most distressing of eye defects, not only because of the lowering of vision involved, but because the want of symmetry in the most expressive feature of the face which results from it has a most unpleasant effect upon the personal appearance. The condition is one which has long baffled ophthalmological science. While the theories as to its cause advanced in the text-books seem to fit some cases, they leave others unexplained, and all methods of treatment are admitted to be very uncertain in their results.

The idea that a lack of harmony in the movements of the eye is due to a corresponding lack of harmony in the strength of the muscles that turn them in their sockets seems such a natural one that this theory was almost universally accepted at one time. Operations based upon it once had a great vogue; but to-day they are advised, by most authorities, only as a last resort. It is true that many persons have benefited by them; but at best

221

222 Squint And Amblyopia: Their Cause

the correction of the squint is only approximate, and in many cases the condition has been made worse, while a restoration of binocular vision - the power of fusing the two visual images into one - is scarcely even hoped for.¹

The muscle theory fitted the facts so badly that when Donders advanced the idea that squint was a condition growing out of refractive errors - hypermetropia being held responsible for the production of convergent and myopia for divergent squint - it was universally accepted. This theory, too, proved unsatisfactory, and now medical opinion is divided between various theories. Hansen-Grut attributed the condition, in the great majority of cases, to a defect, not of the muscles, but of the nerve supply; and this idea has had many supporters. Worth and his disciples lay stress on the lack of a so-called fusion faculty, and have recommended the use of prisms, or other measures, to develop it. Stevens believes that the anomaly results from a wrong shape of the orbit, and as it is impossible to alter this condition, advocates operations for the purpose of neutralizing its influence.

In order to make any of these theories appear consistent it is necessary to explain away a great many troublesome facts. The uncertain result of operations upon the eye muscles is sufficient to cast suspicion on the theory that the condition is due to any abnormality of the muscles, and many cases of marked paralysis of one or more muscles have been observed in which there was no squint. Relief of paralysis, moreover, may not relieve the squint, nor the relief of the squint the paralysis. Worth found

1 The result obtained by the operation is, as a rule, simply cosmetic. The sight of the squinting eye is not influenced by the operation, and in only a few instances is even binocular vision restored. - Fuchs: Text-Book of Ophthalmology, p. 795.

The result of even the most successful squint operation, in long-standing strabismus, is merely cosmetic in the vast majority of cases. - Eversbusch: The Diseases of Children, edited by Pfaunder and Schlossman. English translation by Shaw and La Fetra, second edition, 1912-1914, vol. vii, p. 316.

State Of Vision Not Important Factor 223

so many cases which were not benefited by training designed to improve the fusion faculty that he recommended operations on the muscles in such cases; while Donders, noting that the majority of hypermetropes did not squint, was obliged to assume that hypermetropia

FIG. 53

No. 1. - Reading the Snellen test card with normal vision; visual axes parallel.

No. 2. - The same patient making an effort to see the test card; myopia and convergent squint of the left eye have been produced.

did not cause this condition without the aid of co-operating circumstances.

That the state of the vision is not an important factor in the production of squint is attested by a multitude of facts. It is true, as Donders observed, that squint is usually associated with errors of refraction; but some people squint with a very slight error of refraction. It is also true that many persons with convergent squint

224 Squint And Amblyopia: Their Cause

have hypermetropia; but many others have not. Some persons with convergent squint have myopia. A person may also have convergent squint with one eye normal and one hypermetropic or myopic, or with one eye blind. Usually the vision of the eye that turns in is less than that of the eye which is straight; yet there are cases in which the eye with the poorer vision is straight and the eye with the better vision turned in. With two blind eyes, both eyes may be straight, or one may turn in. With one good eye and one blind eye, both eyes may be straight. The blinder the eye, as a rule, the more marked the squint; but exceptions are frequent, and in rare cases an eye with nearly normal vision may turn in persistently. A squint may disappear and return again, while convergent squint will change into divergent squint and back again. With the same error of refraction, one person will have squint and the other not. A third will squint with a different eye. A fourth will squint first with one eye and then with the other. In a fifth the amount of the squint will vary. One will get well without glasses, or other treatment, and another with these things. These cures may be temporary, or permanent, and the relapses may occur either with or without glasses.

However slight the error of refraction, the vision of many squinting eyes is inferior to that of the straight eye, and for this condition, usually, no apparent or sufficient cause can be found in the constitution of the eye. There is a difference of opinion as to whether this curious defect of vision is the result of the squint, or the squint the result of the defect of vision; but the predominating opinion that it is, at least, aggravated by the squint has been crystallized in the name given to the condition, namely, *amblyopia ex anopsia*, literally *dimsighted*

Facts Versus Theory 225

ness from *non-use* - for in order to avoid the annoyance of double vision the mind is believed to suppress the image of the deviating eye. There are, however, many squinting eyes without amblyopia, while such a condition has been found in eyes that have never squinted.

The literature of the subject is full of the impossibility of curing amblyopia, and in popular writings persons having the care of children are urged to have cases of squint treated early, so that the vision of the squinting eye may not be lost. According to Worth, not much improvement can ordinarily be obtained in amblyopic eyes after the age of six, while Fuchs says, "The function of the retina never again becomes perfectly normal, even if the cause of the visual disturbance is done away with." Yet it is well

known, as the translator of Fuchs points out in an editorial comment upon the above statement,² that if the sight of the good eye is lost at any period of life, the vision of the amblyopic eye will often become normal. Furthermore, an eye may be amblyopic at one time and not at another. When the good eye is covered a squinting eye may be so amblyopic that it can scarcely distinguish daylight from darkness; but when both eyes are open, the vision of the squinting eye may be found to be as good as that of the straight eye, if not better. In many cases, too, the amblyopia will change from one eye to the other.

Double vision occurs very seldom in squint, and when it does it often assumes very curious forms. When the eyes turn in the image seen by the right eye should, according to all the laws of optics, be to the right, and the image seen by the left eye to the left. When the

1 Text-Book of Ophthalmology, p. 633.

2 Cases have been reported, some surely authentic, in which an amblyopic squinting eye has acquired good vision, either through correction of the refraction, or because loss of sight in the good eye has compelled the use of the amblyopic eye. - Ibid.

226 Squint And Amblyopia: Their Cause

eyes turn out the Opposite should be the case. But often the position of the images is reversed, the image of the right eye in convergent squint being seen to the left and that of the left eye to the right, while in divergent squint the opposite is the case. This condition is known as *paradoxical diplopia*. Furthermore, persons with almost normal vision and both eyes perfectly straight may have both kinds of double vision.

All the theories heretofore suggested fail to explain the foregoing facts; but it is a fact that in all cases of squint a strain can be demonstrated, and that the relief of the strain is in all cases followed by the cure of the squint, as well as of the amblyopia and the error of refraction. It is also a fact that all persons with normal eyes can produce squint by a strain to see. It is not a difficult thing to do, and many children derive much amusement from the practice, while it gives their elders unnecessary concern, for fear the temporary squint may become permanent. To produce convergent squint is comparatively easy. Children usually do it by straining to see the end of the nose. The production of divergent squint is more difficulty, but with practice persons with normal eyes become able to turn out either eye, or both, at will. They also become able to turn either eye upward and inward, or upward and outward, at any desired angle. Any kind of squint can, in fact, be produced at will by the appropriate kind of strain. Some persons retain the power to produce voluntary squint more or less permanently. Others quickly lose it if they do not keep in practice. There is usually a lowering of the vision when voluntary squint is produced, and accepted methods of measuring the strength of the muscles seem to show deficiencies corresponding to the nature of the squint.

CHAPTER XXII

SQUINT AND AMBLYOPIA: THEIR CURE

THE evidence is conclusive that squint and amblyopia, like errors of refraction, are purely functional troubles; and since they are always relieved by the relief of the strain with which they are associated, it follows that any of the methods which promote relaxation and central fixation may be employed for their cure. As in the case of errors of refraction, the squint disappears and the amblyopia is corrected just as soon as the patient gains sufficient mental control to remember a perfectly black period. In this way both conditions can be temporarily relieved in a few seconds, their permanent cure being a mere matter of making this temporary state permanent.

One of the best ways of gaining mental control in cases of squint is to learn how to increase the squint, or produce other kinds of squint, voluntarily. In the case illustrated the patient had divergent vertical squint in both eyes. When the left eye was straight the right eye turned out and up, and when the right eye was straight the left eye turned down and out. Both eyes were amblyopic and there was double vision, with the images sometimes on the same side and sometimes on opposite sides. The patient suffered from headaches, and having obtained no relief from glasses, or other methods of treatment, she made up her mind to an operation and consulted Dr. Gudmund J. Gislason, of Grand Forks, N. D., with a view to having one performed. Dr. Gislason, puzzled to find so many muscles apparently

227

228 Squint And Amblyopia: Their Cure

at fault, asked my opinion as to which of them should *be* operated upon. I showed the patient how to make her squint worse, and recommended that Dr. Gislason treat her by eye education without an operation. He did so, and in less than a month the patient had learned to turn both eyes in voluntarily. At first she did this by looking at a pencil held over the bridge of the nose; but later she became able to do it without the pencil, and ultimately she became able to produce every kind of squint at will. The treatment was not pleasant for her, because the production of new kinds of squint, or the making worse of the existing condition, gave her pain; but it effected a complete and permanent cure both of the squint and of the amblyopia. The same method has proved successful with other patients.

Some patients do not know whether they are looking straight at an object or not. These may be helped by watching the deviating eye and directing them to look more nearly in the proper direction. When the deviating eye looks directly at an object the strain to see is less, and the vision is consequently improved. Covering the good eye with an opaque screen, or with ground glass, encourages a more proper use of the squinting eye, especially if the vision of that eye is imperfect.

Children of six years, or younger, can usually be cured of squint by the use of atropine, a one per cent solution being instilled into one or both eyes twice a day, for many months, a year, or longer. The atropine makes it more difficult for the child to see, and makes the sunlight disagreeable. In order to overcome this handicap it has to relax, and the relaxation cures the squint.

The improvement resulting from eye education in cases of squint and amblyopia is sometimes so rapid as to be

Learning To See Worse 229

almost incredible. The following are a few of many other examples that might be quoted:

A girl of eleven had convergent vertical squint of the left eye. The vision of this eye at the distance was 3/200, while at the near-point it was so imperfect that she was unable to read. The vision of the right eye was normal both for the near-point and the distance. She was wearing glasses when she came to the office - convex 4.00 D. S. combined with convex 0.50 D. C., axis 90, for the right eye; and convex 5.50 D. S. for the left eye - but had obtained no benefit from them. When she looked three feet away from the big C with the left eye, she saw it better than when she looked directly at it; but when asked to count my fingers held three feet away from the card, they so attracted her attention that she was able to see the large letter worse. The fact was impressed upon her that she could see the card better when she looked away from it, or she could see it worse, at will; and she was also asked to note that when she saw it worse her vision improved, and when she saw it better her vision declined. After shifting from the card to a point three feet away from it, and seeing the former worse a few times, her vision improved to 10/200. The ability to shift and see **worse** improved by practice so rapidly that in less than ten days her vision was normal in both eyes, and in less than two weeks it had improved to 20/10, while diamond type was read with each eye at from three inches to twenty inches. In less than three weeks her vision for the distance was 20/5, by artificial light, and she read photographic type reductions at two inches, the tests being made with both eyes together and with each eye separately She also read strange test cards as readily as the familiar ones. She

Cured In Three Weeks 231

was advised to continue the treatment at home to prevent a relapse, and at the end of three years none had occurred. During the treatment at the office and practice at home the good eye was covered with an opaque screen, but this was not worn at other times.

A very remarkable case was that of a girl of fourteen who had squinted from childhood. The internal rectus of the right eye had been cut when she was two years old, but still pulled the eye inward. The patient objected to wearing a ground glass over her good eye, because her friends teased her about it and she thought it made her more conspicuous than the squint. One day she lost her glasses in the snow; but her father, who was a man of strong character, immediately provided another pair. Then she announced that she was ill, and couldn't go to school. I told the father that his daughter was hysterical, and simply imagined she was ill to avoid treatment. He insisted that she continue, and as she did not consider herself well enough to come to see me, I called upon her. With the assistance of her father she was made to understand that she would have to continue the treatment until she was cured, and she at once went to work with such energy and intelligence that in half an hour the vision of the squinting and amblyopic eye had improved from 3/200 to 20/30. She also became able to read fine print at twelve inches. She went back to school wearing the ground glass over the good eye; but whenever she wanted to see she looked over the top of it. Her father followed her to school, and insisted that she use the poorer eye instead of the better one. She became convinced that the simplest way out of her troubles would be to follow my instructions, and in less than a week the squint was corrected and she had perfect vision in both

232 Squint And Amblyopia: Their Cure

eyes. At the beginning of the treatment she could not count her fingers at three feet with the poorer eye, and in three weeks, including all the time that she wasted, she had perfect sight. When told that she was cured her

No. 2. - The patient is temporarily cured by the memory of a black period.

main concern seemed to be to know whether she would have to wear the ground glass any more. She was assured that she would not have to do so unless there was a relapse, but there never was any relapse.¹

¹ Bates: L'education de l'oeil dans l'amblyopie ex anopsia, Clin. Opht., Dec. 10, 1912.

Cured In Two Weeks 233

A girl of eight had had amblyopia and squint since childhood. The vision of the right eye was 10/40, while that of the left was 20/30. Glasses did not improve either eye. The patient was seated twenty feet from a Snellen test

card and the right, or poorer eye, was covered with an opaque screen. She was directed to look with her better eye at the large letter on the card and to note its clearness. Next she was told to look at a point three feet to one side of the card, and her attention was called to the fact that she did not then see the large letter so well. The point of fixation was brought closer and closer to the letter, until she appreciated

the fact that her vision was lowered when she looked only a few inches to one side of it. When she looked at a small letter she readily recognized that an eccentric fixation of less than an inch lowered the vision.

After she had learned to increase the amblyopia of the better eye, this eye was covered while she was taught how to lower the vision of the other, or poorer eye, by increasing its eccentric fixation. This was accomplished in a few minutes. She was told that the cause of her defective sight was her habit of looking at objects with a part of the retina to one side of the true center of sight. She was advised to see by looking straight at the Snellen card. In less than half an hour the vision of the left eye became normal, while the right improved from 10/140 to 10/10. The cure was complete in two weeks.

The following case was unusually prolonged, because as soon as one eye had been cured the defect for which it had been treated appeared in the other eye. The patient, a child of ten, had imperfect sight in both eyes, but worse in the right than in the left. The vision of the right eye was restored after some weeks by eye education, when

234 Squint And Amblyopia: Their Cure

the left eye turned in and became amblyopic. The right eye was then covered, and after a few weeks of eye education the left became normal. The right eye then turned in and the vision became defective. It was necessary to educate the eyes alternately, for about a year, before both became

normal at the same time. This patient had congenital paralysis of the external rectus muscle in both eyes, a condition which was apparently not relieved when the squint and amblyopia were cured.

In the following case the patient had an attack of infantile paralysis after her cure, resulting in a relapse, with new and more serious developments, which were, however, quickly cured. The patient, a girl of six, seen first on December 11, 1914, had had divergent squint of the left eye for three years, and had worn glasses for two years without benefit - convex 2.50 D. S. for the right eye, and convex 6.00 D. S. combined with convex 1.00 D. C., axis 90, for the left. The vision of the right eye with glasses was 12/15 and of the left 12/200. Atropine was prescribed for the right eye for the purpose of partially blinding it and thus encouraging a more nearly proper use of the squinting eye, and the usual methods of securing relaxation, such as shifting, palming, the exercise of the memory, etc., were used. On January 13, 1915, the vision without glasses had improved to 10/70 for the right eye, and 10/50 for the left. On February 6, the vision of the right eye was 10/40 and of the left 10/30. The eyes were apparently straight, and scientific tests showed that both were used at the same time (binocular single vision). On April 17, after about four months' treatment, the vision of the left eye was normal, and there was binocular single vision at six inches. On May 1 the vision of the left eye was still normal, and whereas at the be

ginning the patient had been unable to read with it at all, even with glasses, she now read diamond type without glasses at six inches.

On August 16, 1916, the patient had an attack of infantile paralysis which was then epidemic. The sight of both eyes failed, the muscles that turned the eyes in and out were paralyzed, the eyelids twitched, and there was double

vision. Various muscles of the head, the left leg and the left arm were also paralyzed. When she left the hospital after five weeks the left eye was turned in, and the vision of both eyes was so poor that she was unable to recognize her mother. Later she developed alternate convergent squint. On November 2 the paralysis in the right eye subsided, and four weeks later that of the left eye began to improve. On November 9 she returned for treatment without any conspicuous squint, but still suffering from double vision, with the images sometimes on the same side and sometimes on opposite sides. On November 23 the eyes were straight and the vision normal.

On July 11, 1918, the eyes were still straight and the vision normal, and there was binocular single vision at six inches. Although atropine had been used in the right eye every day for more than a year, and intermittently for a much longer time, and the pupil was dilated to the maximum, it read fine print without difficulty at six inches, central fixation overcoming the paralyzing effect of the drug. According to the current theory the accommodation should have been completely paralyzed, making near vision quite impossible. The patient also read fine print with the left eye as well as, or better than, with the right eye.

CHAPTER XXIII.

FLOATING SPECKS: THEIR CAUSE AND CURE

A VERY common phenomenon of imperfect sight is the one known to medical science as *muscae volitantes* or *flying flies*. These floating specks are usually dark or black, but sometimes appear like white bubbles, and in rare cases may assume all the colors of the rainbow. They move somewhat rapidly, usually in curving lines, before the eyes, and always appear to be just beyond the point of fixation. If one tries to look at them directly, they seem to move a little farther away. Hence their name of "*flying flies*."

The literature of the subject is full of speculations as to the origin of these appearances. Some have attributed them to the presence of floating specks - dead cells, or the debris of cells - in the vitreous humor, the transparent substance that fills four-fifths of the eyeball behind the crystalline lens. Similar specks on the surface of the cornea have also been held responsible for them. It has even been surmised that they might be caused by the passage of tears over the cornea. They are so common in myopia that they have been supposed to be one of the symptoms of this condition, although they occur also with other errors of refraction, as well as in eyes otherwise normal. They have been attributed to disturbances of the circulation, the digestion and the kidneys, and because so many insane people have them, have been thought to be an evidence of incipient insanity. The patent-medicine business has thrived upon

A PITIABLE CASE 237

them, and it would be difficult to estimate the amount of mental torture they have caused, as the following cases illustrate.

A clergyman who was much annoyed by the continual appearance of floating specks before his eyes was told by his eye specialist that they were a symptom of kidney disease, and that in many cases of kidney trouble disease of the retina might be an early symptom. So at regular intervals he went to the specialist to have his eyes examined, and when at length the latter died, he looked around immediately for some one else to make the periodical examination. His family physician directed him to me. I was by no means so well known as his previous ophthalmological adviser, but it happened that I had taught the family physician how to use the ophthalmoscope after others had failed to do so. He thought, therefore, that I must know a lot about the use of the instrument, and what the clergyman particularly wanted was some one capable of making a thorough examination of the interior of his eyes and detecting at once any signs of kidney disease that might make their appearance. So he came to me, and at least four times a year for ten years he continued to come.

Each time I made a very careful examination of his eyes, taking as much time over it as possible, so that he would believe that it was careful; and each time he went away happy because I could find nothing wrong. Once when I was out of town he got a cinder in his eye, and went to another oculist to get it out. When I came back late at night I found him sitting on my door step, on the chance that I might return. His story was a pitiable one. The strange doctor had examined his eyes with the ophthalmoscope, and

had suggested the possibility of glau-

238 Floating Specks: Their Cause And Cure

coma, describing the disease as a very treacherous one which might cause him to go suddenly blind and would be agonizingly painful. He emphasized what the patient had previously been told about the danger of kidney disease, suggested that the liver and heart might also be involved, and advised him to have all of these organs carefully examined. I made another examination of his eyes in general and their tension in particular; I had him feel his eyeballs and compare them with my own, so that he might see for himself that they were not becoming hard as a stone; and finally I succeeded in reassuring him. I have no doubt, however, that he went at once to his family physician for an examination of his internal organs.

A man returning from Europe was looking at some white clouds one day when floating specks appeared before his eyes. He consulted the ship's doctor, who told him that the symptom was very serious, and might be the forerunner of blindness. It might also indicate incipient insanity, as well as other nervous or organic diseases. He advised him to consult his family physician and an eye specialist as soon as he landed, which he did. This was twenty-five years ago, but I shall never forget the terrible state of nervousness and terror into which the patient had worked himself by the time he came to me. It was even worse than that of the clergyman, who was always ready to admit that his fears were unreasonable. I examined his eyes very carefully, and found them absolutely normal. The vision was perfect both for the near-point and the distance. The color perception, the fields and the tension were normal; and under a strong magnifying glass I could find no opacities in the vitreous. In short, there were absolutely no symptoms of any

A Common Symptom 239

disease. I told the patient there was nothing wrong with his eyes, and I also showed him an advertisement of a quack medicine in a newspaper which gave a great deal of space to describing the dreadful things likely to follow the appearance of floating specks before the eyes, unless you began betimes to take the medicine in question at one dollar a bottle. I pointed out that the advertisement, which was appearing in all the big newspapers of the city every day, and probably in other cities, must have cost a lot of money, and must, therefore, be bringing in a lot of money. Evidently there must be a great many people suffering from this symptom, and if it were as serious as was generally believed, there would be a great many more blind and insane people in the community than there were. The patient went away somewhat comforted, but at eleven o'clock - his first visit had been at nine - he was back again. He still saw the floating specks, and was still worried about them. I examined his eyes again as carefully as before, and again was able to assure him that there was nothing wrong with them. In the afternoon I was not in my office, but I was told that he was there at three and at five. At seven he came again, bringing with him his family physician, an old friend of mine. I said to the latter:

"Please make this patient stay at home. I have to charge him for his visits, because he is taking up so much of my time; but it is a shame to take his money when there is nothing wrong with him."

What my friend said to him I don't know, but he did not come back again.

I did not know as much about muscae volitantes then as I know now, or I might have saved both of these patients a great deal of uneasiness. I could tell them that

240 Floating Specks: Their Cause And Cure

their eyes were normal, but I did not know how to relieve them of the symptom, which is simply an illusion resulting from mental strain. The specks are associated to a considerable extent with markedly imperfect eyesight, because persons whose eyesight is imperfect always strain to see; but persons whose eyesight is ordinarily normal may see them at times, because no eye has normal sight all the time. Most people can see muscae volitantes when they look at the sun, or any uniformly bright surface, like a sheet of white paper upon which the sun is shining. This is because most people strain when they look at surfaces of this kind. The specks are never seen, in short, except when the eyes and mind are under a strain, and they always disappear when the strain is relieved. If one can remember a small letter on the Snellen test card by central fixation, the specks will immediately disappear, or cease to move; but if one tries to remember two or more letters equally well at one time, they will reappear and move.

Usually the strain that causes muscae volitantes is very easily relieved. A school teacher who had been annoyed by these appearances for years came to me because the condition had grown recently much worse. I was able in half an hour to improve her sight, which had been slightly myopic, to normal, whereupon the specks disappeared. Next day they came back, but another visit to the office brought relief. After that the patient was able to carry out the treatment at home, and had no more trouble.

A physician who suffered constantly from headaches and muscae volitantes was able to read only 20/70 when he looked at the Snellen test card, while the retinoscope showed mixed astigmatism and he saw the specks.

Cured In A Few Days 241

When he looked at a blank wall, or a blank white card, the retinoscope still showed mixed astigmatism and he still saw the specks. When, however, he remembered a black spot as well as he could see it, when looking at these surfaces. there were no specks, and the retinoscope indicated no error of refraction. In a few days he obtained complete relief from the astigmatism, the muscae volitantes, and the headaches, as well as from chronic conjunctivitis. His eyes, which had been partly closed, opened wide, and the sclera became white and clear. He became able to read in moving trains with no inconvenience, and - what impressed him more than anything else - he also became able to sit up all night with patients without having any trouble with his eyes next day.

CHAPTER XXIV

HOME TREATMENT

IT is not always possible for patients to go to a competent physician for relief. As the method of treating eye defects presented in this book is new, it may be impossible to find a physician in the neighborhood who understands it; and the patient may not be able to afford the expense of a long journey, or to take the time for treatment away from home. To such persons I wish to say that it is possible for a large number of people to be cured of defective eyesight without the aid, either of a physician or of anyone else. They can cure themselves, and for this purpose it is not necessary that they should understand all that has been written in this book, or in any other book. All that is necessary is to follow a few simple directions.

Place a Snellen test card on the wall at a distance of ten, fourteen, or twenty feet, and devote half a minute a day, or longer, to reading the smallest letters you can see, with each eye separately, covering the other with the palm of the hand in such a way as to avoid touching the eyeball. Keep a record of the progress made, with the dates. The simplest way to do this is by the method used by oculists, who record the vision in the form of a fraction, with the distance at which the letter is read as the numerator and the distance at which it ought to be read as the denominator. The figures above, or to one side of, the lines of letters on the test card indicate the distance at which these letters should be read by persons with normal eyesight. Thus a vision of 10/200 would

242

Children Quickly Cured 243

mean that the big C, which ought to be read at 200 feet, cannot be seen at a greater distance than ten feet. A vision of 20/10 would mean that the ten line, which the normal eye is not ordinarily expected to read at a greater distance than ten feet, is seen at double that distance. This is a standard commonly attained by persons who have practiced my methods.

Another and even better way to test the sight is to compare the blackness of the letter at the near-point and at the distance, in a dim light and in a good one. With perfect sight, black is not altered by illumination or distance. It appears just as black at the distance as at the near-point, and just as black in a dim light as in a good one. If it does not appear equally black to you under all these conditions, therefore, you may know that your sight is imperfect.

Children under twelve years who have not worn glasses are usually cured of defective eyesight by the above method in three months, six months, or a year. Adults who have never worn glasses are benefited in a very short time in a week or two - and if the trouble is not very bad, may be cured in the course of from three to six months. Children or adults who have worn glasses, however, are more difficult to relieve, and will usually have to practice the methods of gaining relaxation described in other chapters; they will also have to devote considerable time to the treatment.

It is absolutely necessary that the glasses be discarded. No half-way measures can be tolerated, if a cure is desired. Do not attempt to wear weaker glasses, and do not wear glasses for emergencies. Persons who are unable to do without glasses for all purposes are not likely to be able to cure themselves.

244 Home Treatment

Children and adults who have worn glasses will have to devote an hour or longer every day to practice with the test card and the balance of their time to practice on other objects. It will be well for such patients to have two test cards, one to be used at the near-point, where it can be seen best, and the other at ten or twenty feet. The patient will find it a great help to shift from the near card to the distant one, as the unconscious memory of the letters seen at the near-point helps to bring out those seen at the distance.

If you cannot obtain a test card, you can make one for yourself by painting black letters of appropriate size on a white card, or on a piece of white paper. The approximate diameter of these letters, reading from the top of the card to the bottom is: 35 in., 1 3/4 in., 1 1/4 in., 7/8 in., 11/16 in., 1/2 in., 3/8 in., 1/4 in., 3/16 in.

If the patient can secure the aid of some person with normal sight, it will be a great advantage. In fact, persons whose cases are obstinate will find it very difficult, if not impossible, to cure themselves without the aid of a teacher. The teacher, if he is to benefit the patient, must himself be able to derive benefit from the various methods recommended. If his vision is 10/10, he must be able to improve it to 20/10, or more. If he can read fine print at twelve inches, he must become able to read it at six, or at three inches. He must also have sufficient control over his visual memory to relieve and prevent pain. A person who has defective sight, either for the distance or the near-point, and who cannot remember black well enough to relieve and prevent pain, will be unable to be of any material assistance in obstinate cases; and no one will be able to be of any assistance in the application of any method which he himself has not used successfully.

THE DUTY OF PARENTS 245

Parents who wish to preserve and improve the eyesight of their children should encourage them to read the Snellen test card every day. There should, in fact, be a Snellen test card in every family; for when properly used it always prevents myopia and other errors of refraction, always improves the vision, even when this is already normal, and always benefits functional nervous troubles. Parents should improve their own eyesight to normal, so that their children may not imitate wrong methods of using the eyes and will not be subject to the influence of an atmosphere of strain. They should also learn the principles of central fixation sufficiently well to relieve and prevent pain, in order that they may teach their children to do the same. This practice not only makes it possible to avoid suffering, but is a great benefit to the general health.

CHAPTER XXV

CORRESPONDENCE TREATMENT

CORRESPONDENCE treatment is usually regarded as quackery, and it would be manifestly impossible to treat many diseases in this way. Pneumonia and typhoid, for instance, could not possibly be treated by correspondence, even if the physician had a sure cure for these conditions and the mails were not too slow for the purpose. In the case of most diseases, in fact, there are serious objections to correspondence treatment.

But myopia, hypermetropia and astigmatism are functional conditions, not organic, as the text-books teach and as I believed myself until I learned better. Their treatment by correspondence, therefore, has not the drawbacks that exist in the case of most physical derangements. One cannot, it is true, fit glasses by correspondence as well as when the patient is in the office, but even this can be done, as the following case illustrates.

An old colored woman in the wilds of Honduras, far removed from any physician or optician, was unable to read her Bible, and her son, a waiter in New York, asked me if I could not do something for her. The suggestion gave me a distinct shock which I will remember as long as I live. I had never dreamed of the possibility of prescribing glasses for anyone I had not seen and I had, besides, some very disquieting recollections of colored women whom I had tried to fit with glasses at my clinic.

246

Glasses Fitted By Mail 247

If I had so much difficulty in prescribing the proper glasses under favorable conditions, how could I be expected to fit a patient whom I could not even see? The waiter was deferentially persistent, however. He had more faith in my genius than I had, and as his mother was nearing the end of her life, he was very anxious to gratify her last wishes. So, like the unjust judge of the parable, I yielded at last to his importunity, and wrote a prescription for convex 3.00 D. S. The young man ordered the glasses and mailed them to his mother, and by return mail came a very grateful letter stating that they were perfectly satisfactory.

A little later the patient wrote that she couldn't see objects at the distance that were perfectly plain to other people, and asked if some glasses couldn't be sent that would make her see at the distance as well as she did at the near-point. This seemed a more difficult proposition than the first one; but again the son was persistent, and I myself could not get the old lady out of my mind. So again I decided to do what I could. The waiter had told me that his mother had read her Bible long after the age of forty. Therefore I knew she could not have much hypermetropia, and was probably slightly myopic. I knew also that she could not have much astigmatism, for in that case her sight would always have been noticeably imperfect. Accordingly I told her son to ask her to measure very accurately the distance between her eyes

and the point at which she could read her Bible best with her glasses, and to send me the figures. In due time I received, not figures, but a piece of string about a quarter of an inch in diameter and exactly ten inches long. If the patient's vision had been normal for the distance, I knew that she would have been

248 Correspondence Treatment

able to read her Bible best with her glasses at thirteen inches. The string showed that at ten inches she had a refraction of four diopters. Subtracting from this the three diopters of her reading glasses, I got one diopter of myopia. I accordingly wrote a prescription for concave 1.00 D. S., and the glasses were ordered and mailed to Honduras. The acknowledgment was even more grateful than in the case of the first pair. The patient said that for the first time in her life she was able to read signs and see other objects at a distance as well as other people did, and that the whole world looked entirely different to her.

Would anyone venture to say that it was unethical for me to try to help this patient? Would it have been better to leave her in her isolation without even the consolation of Bible reading? I do not think so. What I did for her required only an ordinary knowledge of physiological optics, and if I had failed, I could not have done her much harm.

In the case of the treatment of imperfect sight without glasses there can be even less objection to the correspondence method. It is true that in most cases progress is more rapid and the results more certain when the patient can be seen personally; but often this is impossible, and I see no reason why patients who cannot have the benefit of personal treatment should be denied such aid as can be given them by correspondence. I have been treating patients in this way for years, and often with extraordinary success.

Some years ago an English gentleman wrote to me that his glasses were very unsatisfactory. They not only did not give him good sight, but they increased, instead of lessening, his discomfort. He asked if I could help

Was It Unethical? 249

him, and since relaxation always relieves discomfort and improves the vision, I did not believe that I was doing him an injury in telling him how to rest his eyes. He followed my directions with such good results that in a short time he obtained perfect sight for both the distance and the near-point without glasses, and was completely relieved of his pain. Five years later he wrote me that he had qualified as a sharpshooter in the army. Did I do wrong in treating him by correspondence? I do not think so.

After the United States entered the European war, an officer wrote to me from the deserts of Arizona that the use of his eyes at the near-point caused him great discomfort, which glasses did not relieve, and that the strain had produced granulation of the lids. As it was impossible for him to come to New York, I undertook to treat him by correspondence. He improved very rapidly. The inflammation of the lids was relieved almost immediately, and in about four months he wrote me that he had read one of my own reprints - by no means a short one - in a dim light, with no bad after effects; that the glare of the Arizona

sun, with the Government thermometer registering 114, did not annoy him; and that he could read the ten line on the test card at fifteen feet almost perfectly, while even at twenty feet he was able to make out most of the letters.

A third case was that of a forester in the employ of the U. S. Government. He had myopic astigmatism, and suffered extreme discomfort, which was not relieved either by glasses or by long summers in the mountains, where he used his eyes but little for close work. He was unable to come to New York for treatment, and although I told him that correspondence treat

250 Correspondence Treatment

ment was somewhat uncertain, he said he was willing to risk it. It took three days for his letters to reach me and another three for my reply to reach him, and as letters were not always written promptly on either side, he often did not hear from me more than once in three weeks. Progress under these conditions was necessarily slow; but his discomfort was relieved very quickly, and in about ten months his sight had improved from 20/50 to 20/20.

In almost every case the treatment of patients coming from a distance is continued by correspondence after they return to their homes; and although they do not get on so well as when they are coming to the office, they usually continue to make progress till they are cured.

At the same time it is often very difficult to make patients understand what they should do when one has to communicate with them entirely by writing, and probably all would get on better if they could have some personal treatment. At the present time the number of doctors in different parts of the United States who understand the treatment of imperfect sight without glasses is altogether too few, and my efforts to interest them in the matter have not been very successful.[NOTE: Interesting enough, this the final sentence of this paragraph appears in one of the 1920 editions, but not in another!:] I would consider it a privilege to treat medical men without a fee, and when cured they will be able to assist me in the treatment of patients in their various localities.

CHAPTER XXVI

THE PREVENTION OF MYOPIA IN SCHOOLS:

METHODS THAT FAILED

NO phase of ophthalmology, not even the problem of accommodation, has been the subject of so much investigation and discussion as the cause and prevention of myopia. Since hypermetropia was supposed to be due to a congenital deformation of the eyeball, and astigmatism, until recently, was also supposed to be congenital in most cases, these conditions were not thought to call for any explanation, nor to admit of any prevention; but myopia appeared to be acquired. It therefore presented a problem of immense practical importance to which many eminent men devoted years of labor.

Voluminous statistics were collected regarding its occurrence, and are still being collected. The subject has produced libraries of literature. But very little light is to be gained from the perusal of this material, and for the most part it leaves the reader with an impression of hopeless confusion. It is impossible even to arrive at any conclusion as to the prevalence of the complaint; for not only has there been no uniformity of standards and methods, but none of the investigators has taken into account the fact that the refraction of the eye is not a constant condition, but one which continually varies. There is no doubt, however, that most children, when they begin school, are free from this defect, and that both the number of cases and the degree of the myopia steadily increase as the educational process progresses. Professor Hermann Cohen, of Breslau,

251

252 Prevention Of Myopia: Methods That Failed

whose report of his study of the eyes of upwards of 10,000 children first called general attention to this subject, found scarcely one per cent of myopia in the village schools, twenty to forty per cent in the *Realschulen*, thirty to thirty-five in the gymnasias, and fifty-three to sixty-four in the professional schools. His investigations were repeated in many cities of Europe and America, and his observations, with some difference in percentages, everywhere confirmed.

These conditions were unanimously attributed to the excessive use of the eyes for near work, though, according to the theory that the lens is the agent of accommodation, it was a little difficult to see just why near work should have this effect. On the supposition that accommodation was effected by an elongation of the eyeball, it would have been easy to understand why an excessive amount of accommodation should produce a permanent elongation. But why should an abnormal demand on the accommodative power of the lens produce a change, not in the shape of that body, but in that of the eyeball? Numerous answers to this question have been proposed, but no one has yet succeeded in finding a satisfactory one.¹

In the case of children it has been assumed by many authorities that, since the coats of the eye are softer in youth than in later years, they are unable to withstand a supposed intraocular tension produced by near work. When other errors of refraction, such as hypermetropia and astigmatism, believed to be congenital, were present, it has been supposed that the accommodative struggle for distinct vision produced irritation and strain which encouraged the production of short

1 A satisfactory explanation of the mechanism by which near work produces myopia has not yet been given. - Tscherning: *Physiologic Optics*, p. 86

It is not yet determined how near work changes the longitudinal structure of the eye. - Eversbusch: *The Diseases of Children*, vol. vii, p. 291.

Myopia And The Educational Process 253

sight. When the condition developed in adults, the explanations had to be modified to fit the case, and the fact that a considerable number of cases were observed among peasants and others who did not use their eyes for near work led some authorities to divide the anomaly into two classes, one caused by near work and one unrelated to it, the latter being conveniently attributed to hereditary tendencies.

As it was impossible to abandon the educational system, attempts were made to minimize the supposed evil effects of the reading, writing and other near work which it demanded. Careful and detailed rules were laid down by various authorities as to the sizes of type to be used in schoolbooks, the length of the lines, their distance apart, the distance at which the book should be held, the amount and arrangement of the light, the construction of the desks, the length of time the eyes might be used without a change of focus, etc. Face-rests were even devised to hold the eyes at the prescribed distance from the desk and to prevent stooping, which was supposed to cause congestion of the eyeball and thus to encourage elongation. The Germans, with characteristic thoroughness, actually used these instruments of torture, Cohn never allowing his own children to write without one, "even when sitting at the best possible desk."

The results of these preventive measures were disappointing. Some observers reported a slight decrease in the percentage of myopia in schools in which the prescribed reforms had been made, but on the whole, as Risley has observed in his discussion of the subject in Norris and Oliver's *System of Diseases of the Eye*, "the injurious results of the educational process were not notably arrested."

1 *The Hygiene of the Eye in Schools*, p 127.

254 Prevention Of Myopia: Methods That Failed

"It is a significant, though discouraging, fact," he continues, "that the increase, as found by Cohn both in the percentage and in the degree of myopia, had taken place in those schools where he had especially exerted himself to secure the introduction of hygienic reforms; and the same

FIG. 56. FACE-REST DESIGNED BY KALLMANN-, A GERMAN OPTICIAN.

Cohn never allowed his children to write without it even when sitting at the best possible desk.

is true of the observations of Just, who had examined the eyes of twelve hundred and twenty-nine of the pupils of the two high schools of Zittau, in both of which the hygienic conditions were all that could be desired. He found, nevertheless, that the excellent arrangements had not in any degree lessened the percentage of increase in myopia."¹

¹ School Hygiene, System of Diseases of the Eye, vol. ii, p. 361.

The Theory Breaks Down 255

Further study of the subject has only added to its difficulty, while at the same time it has tended to relieve the schools of much of the responsibility formerly attributed to them for the production of myopia. As the American Encyclopedia of Ophthalmology points out, "the theory that myopia is due to close work aggravated by town life and badly lighted rooms is gradually giving ground before statistics." ¹

In an investigation in London, for instance, in which the schools were carefully selected to reveal any differences that might arise from the various influences, hygienic, social and racial, to which the children were subjected, the proportion of myopia in the best lighted building of the group was actually found to

be higher than in the one where the lighting conditions were worst, although the higher degrees of myopia were more numerous in the latter than in the former. It has also been found that there is just as much myopia in schools where little near work is done as in those in which the demand upon the accommodative power of the eye is greater.² It is only a minority of children, moreover, that become myopic; yet all are subject to practically the same influences, and even in the same child one eye may become myopic while the other remains normal. On the theory that shortsight results from any external influence to which the eye is exposed it is impossible to account for the fact that under the same conditions of life the eyes of different individuals and the two eyes of the same individual behave differently.

Owing to the difficulty of reconciling these facts on the basis of the earlier theories, there is now a growing

1 American Encyclopedia and Dictionary of Ophthalmology, edited by Wood, 1913-1919, vol. xi, p. 8271.

2 Lawson: Brit. Med. Jour., June 18, 1898.

256 Prevention Of Myopia: Methods That Failed

disposition to attribute myopia to hereditary tendencies;¹ but no satisfactory evidence on this point has been brought forward, and the fact that primitive peoples who have always had good eyesight become myopic just as quickly as any others when subjected to the conditions of civilized life, like the Indian pupils at Carlisle,² seems to be conclusive evidence against it.

In spite of the repeated failure of preventive measures based upon the limitation of near work and the regulation of lighting, desks, types, etc., the use of the eyes at the nearpoint under unfavorable conditions is still admitted by most exponents of the heredity theory as probably, if not certainly, a secondary cause of myopia. Sidler-Huguenin, however, whose startling conclusions as to the hopelessness of controlling shortsight were quoted earlier, has observed so little benefit from such precautions that he believes a myope may become an engineer just as well as a farmer, or a forester; and as a result of his experiences with anisometropes, persons with an inequality of refraction between the two organs of vision, he even suggests that the use of myopic eyes may possibly be more favorable to their well-being than their non-use. In 150 cases in which, owing to this inequality and other conditions, the subjects practically used but one eye, the weaker organ, he reports, became gradually more and more myopic, sometimes excessively so, in open defiance of all the accepted theories relating to the matter.

The prevalence of myopia, the unsatisfactoriness of

1 It seems to have been amply demonstrated, by the studies of Motais, Steiger, Miss Barrington, and Karl Pearson, that errors of refraction are inherited. And while the use of the eyes for near work is probably a secondary cause, determining largely the development of the defects it is not the primary cause. -

Cyclopedia of Education, edited by Monroe, 1911-1913.

2 Fox (quoted by Risley): System of Diseases of the Eye, vol. ii, p. 357.

Why Preventive Measures Have Failed 257

all explanations of its origin, and the futility of all methods of prevention, have led some writers of repute to the conclusion that the elongated eyeball is a natural physiological adaptation to the needs of civilization. Against this view two unanswerable arguments can be brought. One is that the myopic eye does not see so well even at the near point as the normal eye, and the other that the defect tends to progression with very serious results, often ending in blindness. If Nature has attempted to adapt the eye to civilized conditions by an elongation of the globe, she has done it in a very clumsy manner. It is true that many authorities assume the existence of two kinds of myopia, one physiological, or at least harmless, and the other pathological; but since it is impossible to say with certainty whether a given case is going to progress or not, this distinction, even if it were correct, would be more important theoretically than practically.

Into such a slough of despond and contradiction have the misdirected labors of a hundred years led us ! But in the light of truth the problem turns out to be a very simple one. In view of the facts given in Chapters V and IX, it is easy to understand why all previous attempts to prevent myopia have failed. All these attempts have aimed at lessening the strain of near work upon the eye, leaving the strain to see distant objects unaffected, and totally ignoring the mental strain which underlies the optical one. There are many differences between the conditions to which the children of primitive man were subjected, and those under which the offspring of civilized races spend their developing years, besides the mere fact that the latter learn things out of books and write things on paper, and the former did not. In the

258 Prevention Of Myopia: Methods That Failed

process of education civilized children are shut up for hours every day within four walls, in the charge of teachers who are too often nervous and irritable. They are even compelled to remain for long periods in the same position. The things they are required to learn may be presented in such a way as to be excessively uninteresting; and they are under a continual compulsion to think of the gaining of marks and prizes rather than the acquisition of knowledge for its own sake. Some children endure these unnatural conditions better than others. Many cannot stand the strain, and thus the schools become the hotbed, not only of myopia, but of all other errors of refraction.

CHAPTER XXVII

THE PREVENTION AND CURE OF MYOPIA AND

OTHER ERRORS OF REFRACTION IN SCHOOLS:

A METHOD THAT SUCCEEDED

YOU cannot see anything with perfect sight unless you have seen it before. When the eye looks at an unfamiliar object it always strains more or less to see that object, and an error of refraction is always produced. When children look at unfamiliar writing or figures on the blackboard, distant maps, diagrams, or pictures, the retinoscope always shows that they are myopic, though their vision may be under other circumstances absolutely normal. The same thing happens when adults look at unfamiliar distant objects. When the eye regards a familiar object, however, the effect is quite otherwise. Not only can it be regarded without strain, but the strain of looking later at unfamiliar objects is lessened.

This fact furnishes us with a means of overcoming the mental strain to which children are subjected by the modern educational system. It is impossible to see anything perfectly when the mind is under a strain, and if children become able to relax when looking at familiar objects, they become able, sometimes in an incredibly brief space of time, to maintain their relaxation when looking at unfamiliar objects.

I discovered this fact while examining the eyes of 1,500 school children at Grand Forks, N. D., in 1903.¹
In

¹ Bates: The Prevention of Myopia in School Children, N. Y. Med. Jour., July 29, 1911.

260 Prevention Of Myopia: Method That Succeeded

many cases children who could not read all of the letters on the Snellen test card at the first test read them at the second or third test. After a class had been examined the children who had failed would sometimes ask for a second test, and then it often happened that they would read the whole card with perfect vision. So frequent were these occurrences that there was no escaping the conclusion that in some way the vision was improved by reading the Snellen test card. In one class I found a boy who at first appeared to be very myopic, but who, after a little encouragement, read all the letters on the test card. The teacher asked me about this boy's vision, because she had found him to be very "nearsighted." When I said that his vision was normal she was incredulous, and suggested that he might have learned the letters by heart, or been prompted by another pupil. He was unable to read the writing or figures on the

blackboard, she said, or to see the maps, charts and diagrams on the walls, and did not recognize people across the street. She asked me to test his sight again, which I did, very carefully, under her supervision, the sources of error which she had suggested being eliminated. Again the boy read all the letters on the card. Then the teacher tested his sight. She wrote some words and figures on the blackboard, and asked him to read them. He did so correctly. Then she wrote additional words and figures, which he read equally well. Finally she asked him to tell the hour by the clock twenty-five feet distant, which he did correctly. It was a dramatic situation, both the teacher and the children being intensely interested. Three other cases in the class were similar, their vision, which had previously been very defective for distant objects, becoming normal in the few moments devoted

No More Defective Eyesight 261

to testing their eyes. It is not surprising that after such a demonstration the teacher asked to have a Snellen test card placed permanently in the room. The children were directed to read the smallest letters they could see from their seats at least once every day, with both eyes together and with each eye separately the other being covered with the palm of the hand in such a way as to avoid pressure on the eyeball. Those whose vision was defective were encouraged to read it more frequently, and, in fact, needed no encouragement to do so after they found that the practice helped them to see the blackboard, and stopped the headaches, or other discomfort, previously resulting from the use of their eyes.

In another class of forty children, between six and eight, thirty of the pupils gained normal vision while their eyes were being tested. The remainder were cured later under the supervision of the teacher by exercises in distant vision with the Snellen card. This teacher had noted every year for fifteen years that at the opening of the school in the fall all the children could see the writing on the blackboard from their seats, but before school closed the following spring all of them without exception complained that they could not see it at a distance of more than ten feet. After learning of the benefits to be derived from the daily practice of distant vision with familiar objects as the points of fixation, this teacher kept a Snellen test card continually in her classroom and directed the children to read it every day. The result was that for eight years no more of the children under her care acquired defective eyesight.

This teacher had attributed the invariable deterioration in the eyesight of her charges during the school year to the fact that her classroom was in the basement and the

262 Prevention Of Myopia: Method That Succeeded

light poor. But teachers with well-lighted classrooms had the same experience, and after the Snellen test card was introduced into both the well-lighted and the poorly lighted rooms, and the children read it every day, the deterioration of their eyesight not only ceased, but the vision of all improved. Vision which had been below normal improved, in most cases, to normal, while children who already had

normal sight, usually reckoned at 20/20, became able to read 20/15, or 20/10. And not only was myopia cured, but the vision for near objects was improved.

At the request of the superintendent of the schools of Grand Forks, Mr. J. Nelson Kelly, the system was introduced into all the schools of the city and was used continuously for eight years, during which time it reduced myopia among the children, which I found at the beginning to be about six per cent, to less than one per cent.

In 1911 and 1912 the same system was introduced into some of the schools of New York City,¹ with an attendance of about ten thousand children. Many of the teachers neglected to use the cards, being unable to believe that such a simple method, and one so entirely at variance with previous teaching on the subject, could accomplish the desired results. Others kept the cards in a closet except when they were needed for the daily eye drill, lest the children should memorize them. Thus they not only put an unnecessary burden upon themselves, but did what they could to defeat the purpose of the system, which is to give the children daily exercise in distant vision with a familiar object as the point of fixation. A considerable number, however, used the system intelligently and persistently, and in less than a year were

¹ Bates: Myopia Prevention by Teachers, N. Y. Med. Jour., Aug. 30, 1913.

Eyesight And Mentality Improved 263

able to present reports showing that of three thousand children with imperfect sight over one thousand had obtained normal vision by its means. Some of these children, as in the case of the children of Grand Forks, were cured in a few minutes. Many of the teachers were also cured, some of them very quickly. In some cases the results of the system were so astonishing as to be scarcely credible.

In a class of mental defectives, where the teacher had kept records of the eyesight of the children for several years, it had been invariably found that their-vision grew steadily worse as the term advanced. As soon as the Snellen test card had been introduced, however, they began to improve. Then came a doctor from the Board of Health who tested the eyes of the children and put glasses on all of them, even those whose sight was fairly good. The use of the card was then discontinued, as the teacher did not consider it proper to interfere while the children were wearing glasses prescribed by a physician. Very soon, however, the children began to lose, break, or discard, their glasses. Some said that the spectacles gave them headaches, or that they felt better without them. In the course of a month or so most of the aids to vision which the Board of Health had supplied had disappeared. The teacher then felt herself at liberty to resume the use of the Snellen test card. Its benefits were immediate. The eyesight and the mentality of the children improved simultaneously, and soon they were all drafted into the regular classes, because it was found that they were making the same progress in their studies as the other children were.

Another teacher reported an equally interesting experience. She had a class of children who did not fit into

264 Prevention Of Myopia: Method That Succeeded

the other grades. Many of them were backward in their studies. Some were persistent truants. All of them had defective eyesight. A Snellen test card was hung in the classroom where all the children could see it, and the teacher carried out my instructions literally. At the end of six months all but two had been cured, and these had improved very much, while the worst incorrigible and the worst truant had become good students. The incorrigible, **who** had previously refused to study, because, he said it gave him a headache to look at a book, or at the blackboard, found out that the test card, in some way, did him a lot of good; and although the teacher had asked him to read it but once a day, he read it whenever he felt uncomfortable. The result was that in a few weeks his vision had become normal and his objection to study had disappeared. The truant had been in the habit of remaining away from school two or three days every week, and neither his parents nor the truant officer had been able to do anything about it. To the great surprise of his teacher he never missed a day after having begun to read the Snellen test card. When she asked for an explanation, he told her that what had driven him away from school was the pain that came in his eyes whenever he tried to study, or to read the writing on the blackboard. After reading the Snellen test card, he said, his eyes and head were rested and he was able to read without any discomfort.

To remove any doubts that might arise as to the cause of the improvement noted in the eyesight of the children, comparative tests were made with and without cards. In one case six pupils with defective sight were examined daily for one week without the use of the test card. No improvement took place. The card was then restored to its place, and the group was instructed to read it every

Must Have Prevented Myopia 265

day. At the end of a week all had improved and five were cured. In the case of another group of defectives the results were similar. During the week that the card was not used no improvement was noted; but after a week of exercises in distant vision with the card all showed marked improvement, and at the end of a month all were cured. In order that there might be no question as to the reliability of the records of the teachers some of the principals asked the Board of Health to send an inspector to test the vision of the pupils, and whenever this was done the records were found to be correct.

One day I visited the city of Rochester, and while there I called on the Superintendent of Public Schools and told him about my method of preventing myopia. He was very much interested and invited me to introduce it in one of his schools. I did so, and at the end of three months a report was sent to me showing that the vision of all the children had improved, while quite a number of them had obtained normal vision in both eyes.

The method has been used in a number of other cities and always with the same result. The vision of all

the children improved, and many of them obtained normal vision in the course of a few minutes, days, weeks, or months.

It is difficult to prove a negative proposition, but since this system improved the vision of all the children who used it, it follows that none could have grown worse. It is therefore obvious that it must have prevented myopia. This cannot be said of any method of preventing myopia in schools which had previously been tried. All other methods are based on the idea that it is the excessive use of the eyes for near work that causes myopia, and all of them have admittedly failed.

It is also obvious that the method must have prevented

266 Prevention Of Myopia: Method That Succeeded

other errors of refraction, a problem which previously had not even been seriously considered, because hypermetropia is supposed to be congenital, and astigmatism was until recently supposed also to be congenital in the great majority of cases. Anyone who knows how to use a retinoscope may, however, demonstrate in a few minutes that both of these conditions are acquired; for no matter how astigmatic or hypermetropic an eye may be, its vision always becomes normal when it looks at a blank surface without trying to see. It may also be demonstrated that when children are learning to read, write, draw, sew, or to do anything else that necessitates their looking at unfamiliar objects at the nearpoint, hypermetropia, or hypermetropic astigmatism, is always produced. The same is true of adults. These facts have not been reported before, so far as I am aware, and they strongly suggest that children need, first of all, eye education. They must be able to look at strange letters or objects at the near-point without strain before they can make much progress in their studies, and in every case in which the method has been tried it has been proven that this end is attained by daily exercise in distant vision with the Snellen test card. When their distant vision has been improved by this means children invariably become able to use their eyes without strain at the near-point.

The method succeeded best when the teacher did not wear glasses. In fact, the effect upon the children of a teacher who wears glasses is so detrimental that no such person should be allowed to be a teacher, and since errors of refraction are curable, such a ruling would work no hardship on anyone. Not only do children imitate the visual habits of a teacher who wears glasses, but the nervous strain of which the defective sight is an expression produces in them a similar condition. In classes of the same grade, with the same lighting, the sight of children whose teachers did not wear glasses has always been found to be better than the sight of children whose teachers did wear them.

Why Should Our Children Suffer? 267

In one case I tested the sight of children whose teacher wore glasses, and found it very imperfect The

teacher went out of the room on an errand, and after she had gone I tested them again. The results were very much better. When the teacher returned she asked about the sight of a particular boy, a very nervous child, and as I was proceeding to test him she stood before him and said, "Now, when the doctor tells you to read the card, do it." The boy couldn't see anything. Then she went behind him, and the effect was the same as if she had left the room. The boy read the whole card.

Still better results would be obtained if we could reorganize the educational system on a rational basis. Then we might expect a general return of that primitive acuity of vision which we marvel at so greatly when we read about it in the memoirs of travellers. But even under existing conditions it has been proven beyond the shadow of a doubt that errors of refraction are no necessary part of the price we must pay for education.

There are at least ten million children in the schools of the United States who have defective sight. This condition prevents them from taking full advantage of the educational opportunities which the State provides. It undermines their health and wastes the taxpayers' money. If allowed to continue, it will be an expense and a handicap to them throughout their lives. In many cases it will be a source of continual misery and suffering. And

268 Prevention Of Myopia: Method Test Succeeded

yet practically all of these cases could be cured and the development of new ones prevented by the daily reading of the Snellen test card.

Why should our children be compelled to suffer and wear glasses for want of this simple measure of relief? It costs practically nothing. In fact, it would not be necessary, in some cases, as in the schools of New York City, even to purchase the Snellen test cards, as they are already being used to test the eyes of the children. Not only does it place practically no additional burden upon the teachers, but, by improving the eyesight, health, disposition and mentality of their pupils, it greatly lightens their labors. No one would venture to suggest, further, that it could possibly do any harm. Why, then, should there be any delay about introducing it into the schools? If there is still thought to be need for further investigation and discussion, we can investigate and discuss just as well after the children get the cards as before, and by adopting that course we shall not run the risk of needlessly condemning another generation to that curse which heretofore has always dogged the footsteps of civilization, namely, defective eyesight. I appeal to all who read these lines to use whatever influence they possess toward the attainment of this end.

DIRECTIONS

FOR USING THE SNELLEN TEST CARD FOR THE PREVENTION AND CURE OF IMPERFECT SIGHT

IN SCHOOLS

The Snellen Test Card is placed permanently upon the wall of the classroom, and every day the children silently read the smallest letters they can see from their seats with each eye separately, the other being covered

How To Use The Card 269

with the palm of the hand in such a way as to avoid pressure on the eyeball. This takes no appreciable amount of time, and is sufficient to improve the sight of all children in one week and to cure all errors of refraction after some months, a year, or longer.

Children with markedly defective vision should be encouraged to read the card more frequently. Children wearing glasses should not be interfered with, as they are supposed to be under the care of a physician, and the practice will do them little or no good while the glasses are worn.

While not essential, it is a great advantage to have records made of the vision of each pupil at the time when the method is introduced, and thereafter at convenient intervals - annually or more frequently. This may be done by the teacher.

The records should include the name and age of the pupils, the vision of each eye tested at twenty feet, and the date. For example:

John Smith, 10, Sept. 15, 1919

R. V. (vision of the right eye) 20/40

L. V. (vision of the left eye) 20/20

John Smith, 11, January 1, 1920

R. V. 20/30

L. V. 20/15

A certain amount of supervision is absolutely necessary. At least once a year some one who understands the method should visit each classroom for the purpose of answering questions, encouraging the teachers to continue the use of the method, and making some kind of a report to the proper authorities. It is not necessary that either the supervisor, the teachers, or the children, should understand anything about the physiology of the eye.

CHAPTER XXVIII

TINE STORY OF EMILY

THE efficacy of the method of treating imperfect sight without glasses presented in this book has been demonstrated in thousands of cases, not only in my own practice but in that of many persons of whom I may not even have heard; for almost all patients, when they are cured, proceed to cure others. At a social gathering one evening, a lady told me that she had met a number of my patients; but when she mentioned their names, I found that I did not remember any of them and said so.

"That is because you cured them by proxy," she said. "You didn't directly cure Mrs. Jones or Mrs. Brown, but you cured Mrs. Smith, and Mrs. Smith cured the other ladies. You didn't treat Mr. and Mrs. Simpkins, or Mr. Simpkins' mother and brother; but you may remember that you cured Mr. Simpkins' boy of a squint, and he cured the rest of the family."

In schools where the Snellen test card was used to prevent and cure imperfect sight, the children, after they were cured themselves, often took to the practice of ophthalmology with the greatest enthusiasm and success, curing their fellow students, their parents and their friends. They made a kind of game of the treatment, and the progress of each school case was watched with the most intense interest by all the children. On a bright day, when the patients saw well, there was great rejoicing, and on a dark day there was corresponding depression. One girl cured twenty-six children in six months; another cured twelve in three months; a third

270

Apparent Blindness Cured 271

developed quite a varied ophthalmological practice, and did things of which older and more experienced practitioners might well have been proud. Going to the school which she attended one day, I asked this girl about her sight, which had been very imperfect. She replied that it was now very good, and that her headaches were quite gone. I tested her sight and found it normal. Then another child whose sight had also been very poor spoke up.

"I can see all right too," she said. "Emily" - indicating girl No. 1 - "cured me."

"Indeed!" I replied. "How did she do that?"

The second girl explained that Emily had had her read the card, which she could not see at all from the back of the room, at a distance of a few feet. The next day she had moved it a little farther away, and so

on, until the patient was able to read it from the back of the room, just as the other children did. Emily now told her to cover the right eye and read the card with her left, and both girls were considerably upset to find that the uncovered eye was apparently blind. The school doctor was consulted and said that nothing could be done. The eye had been blind from birth and no treatment would do any good.

Nothing daunted, however, Emily undertook the treatment. She told the patient to cover her good eye and go up close to the card, and at a distance of a foot or less it was found that she could read even the small letters. The little practitioner then proceeded confidently as with the other eye, and after many months of practice the patient became the happy possessor of normal vision in both eyes. The case had, in fact, been simply one of high myopia, and the school doctor, not being a specialist, had not detected the difference between this condition and blindness.

272 The Story Of Emily

In the same classroom, there had been a little girl with congenital cataract, but on the occasion of my visit the defect had disappeared. This, too, it appeared, was Emily's doing. The school doctor had said that there was no help for this eye except through operation, and as the sight of the other eye was pretty good, he fortunately did not think it necessary to urge such a course. Emily accordingly took the matter in hand. She had the patient stand close to the card, where, with the good eye covered, she was unable to see even the big C. Emily now held the card between the patient and the light, and moved it back and forth. At a distance of three or four feet this movement could be observed indistinctly by the patient. The card was then moved farther away, until the patient became able to see it move at ten feet and to see some of the larger letters indistinctly at a less distance. Finally; after six months, she became able to read the card with the bad eye as well as with the good one. After testing her sight and finding it normal in both eyes, I said to Emily:

"You are a splendid doctor. You beat them all. Have you done anything else?"

The child blushed, and turning to another of her classmates, said:

"Mamie, come here."

Mamie stepped forward and I looked at her eyes. There appeared to be nothing wrong with them.

"I cured her," said Emily.

"What of ?" I inquired.

"Cross eyes," replied Emily.

"How?" I asked, with growing astonishment.

Emily described a procedure very similar to that adopted in the other cases. Finding that the sight of the crossed eye was very poor, so much so, indeed, that poor

An Astonishing Record 273

Mamie could see practically nothing with it, the obvious course of action seemed to her to be the restoration of its sight; and, never having read any medical literature, she did not know that this was impossible. So she went to it. She had Mamie cover her good eye and practice the bad one at home and at school, until at last the sight became normal and the eye straight. The school doctor had wanted to have the eye operated upon, I was told, but, fortunately, Mamie was "scared" and would not consent. And here she was with two perfectly good, straight eyes.

"Anything else?" I inquired, when Mamie's case had

been disposed of. Emily blushed again, and said:

"Here's Rose. Her eyes used to hurt her all the time, and she couldn't see anything on the blackboard. Her headaches used to be so bad that she had to stay away from school every once in a while. The doctor gave her glasses; but they didn't help her, and she wouldn't wear them. When you told us the card would help our eyes I got busy with her. I had her read the card close up, and then I moved it farther away, and now she can see all right, and her head doesn't ache any more. She comes to school every day, and we all thank you very much."

This was a case of compound hypermetropic astigmatism.

Such stories might be multiplied indefinitely. Emily's astonishing record cannot, it is true, be duplicated; but lesser cures by cured patients have been very numerous, and serve to show that the benefits of the method of preventing and curing defects of vision in the schools which is presented in the foregoing chapter would be far-reaching. Not only errors of refraction would be cured, but many more serious defects; and not only the children would be helped, but their families and friends also.

CHAPTER XXIX

MIND AND VISION

POOR sight is admitted to be one of the most fruitful causes of retardation in the schools. It is estimated¹ that it may reasonably be held responsible for a quarter of the habitually "left-backs," and it is commonly assumed that all this might be prevented by suitable glasses.

There is much more involved in defective vision, however, than mere inability to see the blackboard, or to use the eyes without pain or discomfort. Defective vision is the result of an abnormal condition of the mind; and when the mind is in an abnormal condition it is obvious that none of the processes of education can be conducted with advantage. By putting glasses upon a child we may, in some cases, neutralize the effect of this condition upon the eyes, and by making the patient more comfortable may improve his mental faculties to some extent; but we do not alter fundamentally the condition of the mind, and by confirming it in a bad habit we may make it worse.

It can easily be demonstrated that among the faculties of the mind which are impaired when the vision is impaired is the memory; and as a large part of the educational process consists of storing the mind with facts, and all the other mental processes depend upon one's

¹ School Health News, published by the Department of Health of New York City, February, 1919.

Memory In Relation To Vision 275

knowledge of facts, it is easy to see how little is accomplished by merely putting glasses on a child that has "trouble with its eyes." The extraordinary memory of primitive people has been attributed to the fact that owing to the absence of any convenient means of making written records they had to depend upon their memories, which were strengthened accordingly; but in view of the known facts about the relation of memory to eyesight it is more reasonable to suppose that the retentive memory of primitive man was due to the same cause as his keen vision, namely, a mind at rest.

The primitive memory as well as primitive keenness of vision, has been found among civilized people; and if the necessary tests had been made it would doubtless have been found that they always occur together, as they did in a case which recently came under my observation. The subject was a child of ten with such marvelous eyesight that she could see the moons of Jupiter with the naked eye, a fact which was demonstrated by her drawing a diagram of these satellites which exactly corresponded to the diagrams made by persons who had used a telescope. Her memory was equally remarkable. She could recite the whole content of a book after reading it, as Lord Macaulay is said to have done, and she learned more Latin in a few days without a teacher than her sister, who had six diopters of myopia, had been able to do in several years. She remembered five years afterward what she ate at a restaurant, she

recalled the name of the waiter, the number of the building and the street in which it stood. She also remembered what she wore on this occasion and what every one else in the party wore. The same was true of every other event which had awakened her interest in any way, and it was

276 Mind And Vision

a favorite amusement in her family to ask her what the menu had been and what people had worn on particular occasions.

When the sight of two persons is different it has been found that their memories differ in exactly the same degree. Two sisters, one of whom had only ordinary good vision, indicated by the formula 20/20, while the other had 20/10, found that the time it took them to learn eight verses of a poem varied in almost exactly the same ratio as their sight. The one whose vision was 20/10 learned eight verses of the poem in fifteen minutes, while the one whose vision was only 20/20 required thirty-one minutes to do the same thing. After palming, the one with ordinary vision learned eight more verses in twenty-one minutes, while the one with 20/10 was able to reduce her time by only two minutes, a variation clearly within the limits of error. In other words, the mind of the latter being already in a normal or nearly normal condition, she could not improve it appreciably by palming, while the former, whose mind was under a strain, was able to gain relaxation, and hence improve her memory, by this means.

Even when the difference in sight is between the two eyes of the same person it can be demonstrated, as was pointed out in the chapter on "Memory as an Aid to Vision," that there is a corresponding difference in the memory, according to whether both eyes are open, or the better eye closed.

Under the present educational system there is a constant effort to compel the children to remember. These efforts always fail. They spoil both the memory and the sight. The memory cannot be forced any more than the vision can be forced. We remember without effort,

Interest Necessary To Good Vision 277

just as we see without effort, and the harder we try to remember or see the less we are able to do so.

The sort of things we remember are the things that interest us, and the reason children have difficulty in learning their lessons is because they are bored by them. For the same reason, among others, their eyesight becomes impaired, boredom being a condition of mental strain in which it is impossible for the eye to function normally.

Some of the various kinds of compulsion now employed in the educational process may have the effect of awakening interest. Betty Smith's interest in winning a prize, for instance, or in merely getting ahead

of Johnny Jones, may have the effect of rousing her interest in lessons that have hitherto bored her, and this interest may develop into a genuine interest in the acquisition of knowledge; but this cannot be said of the various fear incentives still so largely employed by teachers. These, on the contrary, have the effect, usually, of completely paralyzing minds already benumbed by lack of interest, and the effect upon the vision is equally disastrous.

The fundamental reason, both for poor memory and poor eyesight in school children, in short, is our irrational and unnatural educational system. Montessori has taught us that it is only when children are interested that they can learn. It is equally true that it is only when they are interested that they can see. This fact was strikingly illustrated in the case of one of the two pairs of sisters mentioned above. Phebe, of the keen eyes, who could recite whole books if she happened to be interested in them, disliked mathematics and anatomy extremely, and not only could not learn them but became myopic when they were presented to her mind. She

278 Mind And Vision

could read letters a quarter of an inch high at twenty feet in a poor light, but when asked to read figures one to two inches high in a good light at ten feet she miscalled half of them. When asked to tell how much 2 and 3 made, she said "4," before finally deciding on "5": and all the time she was occupied with this disagreeable subject the retinoscope showed that she was myopic. When I asked her to look into my eye with the ophthalmoscope, she could see nothing, although a much lower degree of visual acuity is required to note the details of the interior of the eye than to see the moons of Jupiter.

Shortsighted Isabel, on the contrary, had a passion for mathematics and anatomy, and excelled in those subjects. She learned to use the ophthalmoscope as easily as Phebe had learned Latin. Almost immediately she saw the optic nerve, and noted that the center was whiter than the periphery. She saw the light-colored lines, the arteries; and the darker ones, the veins; and she saw the light streaks on the blood-vessels. Some specialists never become able to do this, and no one could do it without normal vision. Isabel's vision, therefore, must have been temporarily normal when she did it. Her vision for figures, although not normal, was better than for letters.

In both these cases the ability to learn and the ability to see went hand in hand with interest. Phebe could read a photographic reduction of the Bible and recite what she had read verbatim, she could see the moons of Jupiter and draw a diagram of them afterwards, because she was interested in these things; but she could not see the interior of the eye, nor see figures even half as well as she saw letters, because these things bored her. When, however, it was suggested to her that it would be

Central Fixation Of The Mind 279

a good joke to surprise her teachers, who were always reproaching her for her backwardness in mathematics, by taking a high mark in a coming examination, her interest in the subject awakened and she contrived to learn enough to get seventy-eight per cent. In Isabel's case letters were antagonistic. She was not interested in most of the subjects with which they dealt, and, therefore, she was backward in those subjects, and had become habitually myopic. But when asked to look at objects which aroused an intense interest her vision became normal.

When one is not interested, in short, one's mind is not under control, and without mental control one can neither learn nor see. Not only the memory but all other mental faculties are improved when the eyesight becomes normal. It is a common experience with patients cured of defective sight to find that their ability to do their work has improved.

The teacher whose letter is quoted in a later chapter testified that after gaining perfect eyesight she "knew better how to get at the minds of the pupils," was "more direct, more definite, less diffused, less vague," possessed, in fact, "central fixation of the mind." In another letter she said: "The better my eyesight becomes the greater is my ambition. On the days when my sight is best have the greatest anxiety. to do things."

Another teacher reported that one of her pupils used to sit doing nothing all day long, and apparently was not interested in anything. After the test card was introduced into the classroom and his sight improved, he became anxious to learn, and speedily developed into one of the best students in the class. In other words his eyes and his mind became normal together.

A bookkeeper nearly seventy years of age who had

280 Mind And Vision

worn glasses for forty years found after he had gained perfect sight without glasses that he could work more rapidly and accurately and with less fatigue than ever in his life before. During busy seasons, or when short of help, he has worked for some weeks at a time from 7 a. m. until 11 p. m., and he insisted that he felt less tired at night after he was through than he did in the morning when he started. Previously, although he had done more work than any other man in the office, it always tired him very much. He also noticed an improvement in his temper. Having been so long in the office, and knowing so much more about the business than his fellow employees, he was frequently appealed to for advice. These interruptions, before his sight became normal, were very annoying to him, and often caused him to lose his temper. Afterward, however, they caused him no irritation whatever.

In another case, symptoms of insanity were relieved when the vision became normal. The patient was a physician who had been seen by many nerve and eye specialists before he came to me, and who consulted me at last, not because he had any faith in my methods, but because nothing else seemed to be left for him to do. He brought with him quite a collection of glasses prescribed by different men, no two of them being alike. He had worn glasses, he told me, for many months at a time without benefit, and

then he had left them off and had been apparently no worse. Outdoor life had also failed to help him. On the advice of some prominent neurologists he had even given up his practice for a couple of years to spend the time upon a ranch, but the vacation had done him no good.

I examined his eyes and found no organic defects and

Under Terrific Strain 281

no error of refraction. Yet his vision with each eye was only three-fourths of the normal, and he suffered from double vision and all sorts of unpleasant symptoms. He used to see people standing on their heads, and little devils dancing on the tops of the high buildings. He also had other illusions too numerous to be mentioned here. At night his sight was so bad that he had difficulty in finding his way about, and when walking along a country road he believed that he saw better when he turned his eyes far to one side and viewed the road with the side of the retina instead of with the center. At variable intervals, without warning and without loss of consciousness, he had attacks of blindness. These caused him great uneasiness, for he was a surgeon with a large and lucrative practice, and he feared that he might have an attack while operating.

His memory was very poor. He could not remember the color of the eyes of any member of his family, although he had seen them all daily for years. Neither could he recall the color of his house, the number of rooms on the different floors, or other details. The faces and names of patients and friends he recalled with difficulty, or not at all.

His treatment proved to be very difficult, chiefly because he had an infinite number of erroneous ideas about physiological optics in general and his own case in particular, and insisted that all these should be discussed; while these discussions were going on he received no benefit. Every day for hours at a time over a long period he talked and argued. His logic was wonderful, apparently unanswerable, and yet utterly wrong.

His eccentric fixation was of such high degree that when he looked at a point forty-five degrees to one side from

282 Mind And Vision

of the big C on the Snellen test card, he saw the letter just as black as when he looked directly at it. The strain to do this was terrific, and produced much astigmatism; but the patient was unconscious of it, and could not be convinced that there was anything abnormal in the symptom. If he saw the letter at all, he argued, he must see it as black as it really was, because he was not color-blind. Finally he became able to look away from one of the smaller letters on the card and see it worse than when he looked directly at it.

It took eight or nine months to accomplish this, but when it had been done the patient said that it seemed as if a great burden had been lifted his mind. He experienced a wonderful feeling of rest and relaxation throughout his whole body.

When asked to remember black with his eyes closed and covered he said he could not do so, and he saw every color but the black which one ought normally to see when the optic nerve is not subject to the stimulus of light. He had, however, been an enthusiastic football player at college, and he found at last that he could remember a black football. I asked him to imagine that this football had been thrown into the sea and that it was being carried outward by the tide, becoming constantly smaller but no less black. This he was able to do, and the strain floated with the football, until, by the time the latter had been reduced to the size of a period in a newspaper, it was entirely gone. The relief continued as long as he remembered the black spot, but as he could not remember it all the time, I suggested another method of gaining permanent relief. This was to make his sight voluntarily worse, a plan against which he protested with considerable emphasis.

"Good heavens!" he said. "Isn't my sight bad enough without making it worse?"

A Problem Not To Be Solved By Glasses 283

After a week of argument, however, he consented to try the method, and the result was extremely satisfactory. After he had learned to see two or more lights where there was only one, by straining to see a point above the light while still trying to see the light as well as when looking directly at it, he became able to avoid the unconscious strain that had produced his double and multiple vision and was not troubled by these superfluous images any more. In a similar manner other illusions were prevented.

One of the last illusions to disappear was his belief that an effort was required to remember black. His logic on this point was overwhelming, but after many demonstrations he was convinced that no effort was required to let go, and when he realized this, both his vision and his mental condition immediately improved.

He finally became able to read 20/10 or more, and although more than fifty-five years of age, he also read diamond type at from six to twenty-four inches. His night blindness was relieved, his attacks of day blindness ceased, and he told me the color of the eyes of his wife and children. One day he said to me:

"Doctor, I thank you for what you have done for my sight; but no words can express the gratitude I feel for what you have done for my mind."

Some years later he called with his heart full of gratitude, because there had been no relapse.

From all these facts it will be seen that the problems of vision are far more intimately associated with the problems of education than we had supposed, and that they can by no means be solved by putting concave, or convex, or astigmatic lenses before the eyes of the children.

CHAPTER XXX

NORMAL SIGHT AND THE RELIEF OF PAIN FOR
SOLDIERS AND SAILORS

THE Great War is over, and among the millions of brave men who- laid down their lives in the cruel conflict there were some who thought that they were doing so that wars might be no more. But the earth IS still filled with wars and rumors of war, and in the countries of the victorious Allies the spirit of militarism is rampant. In the United States we are being urged to increased naval and military expenditure, and there is a strong demand for universal military training. Whether it is necessary for us to join in the competition of armaments which resulted in the terrific convulsion through which we have just passed, is a question which need not be entered into here; but if we are going to do so, we may as well have soldiers and sailors with normal sight; and if we attain this end we shall not have borne the burdens of militarism and navalism altogether in vain.

After the United States entered the recent war, I had the privilege of making it possible for many young men who had been unable to meet the visual requirements for admission to the army and navy, or to favorite branches of these services, to gain normal vision; and seeing no reason why such benefits should be confined to the few, I supplied the Surgeon General of the Army with a plan whereby with far less trouble and expense than was involved by the optical service upon which

A Leading Cause Of Rejection 285

we were then depending to make the worst of the enlisted eye-defectives available for service at the front, normal vision without glasses might have been insured to all soldiers and sailors. This plan was not acted upon, and I now present it, with some modifications, to the public, in the hope that enough people will see its military value to secure its adoption.

If we are to have universal military training, we shall find, as the nations of Europe have found, that it will be necessary to take measures to provide suitable material for such training. In Europe this necessity has resulted in extensive systems of child care, but in this book we are concerned only with the question of eyesight. In the first draft for the recent war, defective eyesight was the greatest single cause for rejection, while in later drafts it became one of three leading causes only because of an enormous lowering of an already low standard. Yet there is no impediment to the raising of an army which might be more easily removed. If we want our children to grow big enough to be soldiers, without losing most of their teeth and developing flat feet and crooked spines before they reach the military age, we shall have to make some arrangements, as every one of the advanced countries of Europe has done, for providing material as well as intellectual food in the schools. We shall have to employ school physicians on full time, and pay them enough to compensate men of eminence for the loss of private practice. We

shall also have to see that the children are not sacrificed to the ignorance or poverty of their parents before they reach school age. But to preserve their eyesight it is only necessary to place Snellen test cards in every school classroom, and see that the children read them every day. With this simple

286 Normal Sight For Soldiers And Sailors

system of eye education beginning in the kindergarten and extending through the whole educational process up to the university and the professional school, it would soon be found that the young men of the country, on arrival at the military age, were practically free from eye defects.

But some years must elapse before this happy result can be achieved; and all eyes, moreover, no matter how good their vision, are benefited by the daily practice of the art of seeing, while by such practice those visual lapses to which every eye is subject, and which are particularly dangerous in military and naval operations, are either prevented or minimized. Therefore a system of eye education for training camps and the front should also be provided. For this purpose the method used in the schools could be modified.

Under conditions of actual warfare, or on the parade grounds of training camps, a Snellen test card might be impracticable; but there are other letters, or small objects,. On the uniforms, on the guns, on the wagons, or elsewhere, which would serve the purpose equally well.

Letters or objects which require a vision of 20/20 should be selected by some one who has been taught what 20/20 means, and the men should be required to regard these letters or objects twice a day. After reading the letters they should be directed to cover their closed eyes with the palms of their hands to shut out all the light, and remember some color, preferably black, as well as they are able to see it, for half a minute. Then they should read the letters again and note any improvement in vision. The whole procedure would take not more than a minute. It should be made part of the regular drill, night and morning, and men with imperfect sight

No Soldier Should Wear Glasses 287

should be encouraged to repeat it as many times a day as convenient. They will need no urging; for imperfect vision is a bar to advancement, and excludes from the favorite branch of the service, namely, aviation.

In each regiment every ten men should be under the supervision of one man who understands the method, and who must possess normal vision without glasses. He should carry a pocket test card, consisting of a few of the smaller letters, and should test the vision of the men at the beginning of the training, and thereafter at intervals of three months, reporting the results to the medical officer in charge.

Since errors of refraction are curable, no soldier should be allowed to wear glasses; but if the use of these aids to vision is permitted, the men wearing them should not be required to take part in the eye drills. as the method will do them no good under these conditions. When they see the benefits of eye education, however, they may wish to share them, and will, no doubt, be willing to submit to the inconvenience resulting, temporarily, from going without their glasses.

In military colleges the same method could be used as in the schools; but a daily eye drill should also form part of the maneuvers on the parade ground, so that the students may be prepared to use it later in training camps, or at the front.

To aviators, whether engaged in military or civilian operations, or whether they are flying merely for pleasure, eye education is of particular importance. Accidents to aviators, otherwise unaccountable, are easily explained when one understands how dependent the aviator is upon his eyesight, and how easily perfect vision may be lost amid the unaccustomed surroundings, the dangers and

288 Normal Sight For Soldiers And Sailors

hardships of the upper air. It was formerly supposed that aviators maintained their equilibrium in the air by the aid of the internal ear; but it is now becoming evident from the testimony of aviators who have found themselves emerging from a cloud with one wing down, or even with their machines turned completely upside down, that equilibrium is maintained almost entirely, if not altogether, by the sense of sight. If the aviator loses his sight, therefore, he is lost, and we have one of those "unaccountable" accidents which, during the war, were so unhappily common in the air service. All aviators, therefore, should make a daily practice of reading small, familiar letters, or observing other small, familiar objects, at a distance of ten feet or more. In addition, they should have a few small letters, or a single letter, on their machines, at a distance of five, ten, or more feet from their eyes, arrangements being made to illuminate them for night flying and fogs, and should read them frequently while in the air. This would greatly lessen the danger of visual lapses, with their accompanying loss of equilibrium and judgment.

As has already been pointed out, eye education not only improves the sight, but affords a means by which pain, fatigue, the symptoms of disease and other discomforts, can be relieved. For this latter purpose it is of the greatest value to soldiers and sailors; and if, during the recent war, they had only understood the simple and always available method of relieving pain by the aid of the memory, not only much suffering, but many deaths from the destructive effects of pain upon the body, might have been prevented. A soldier in a flooded trench, if he can remember black perfectly, will know the temperature of

1 Anderson Lancet, March 16, 1918, 398: Hucks: Scientific American.

the water, but will not suffer from cold. Under the same conditions he may succumb from weakness on the march, but will not feel fatigue. He may die of hemorrhage, but he will die painlessly. It will not be necessary to give him morphine to relieve his pain; and thus to the dangers of the battlefields will not be added the danger of returning to civil life under the handicap of a lifelong morphine habit.

This danger, there is reason to believe, assumed enormous proportions during the war. The Germans used a bullet which broke when it struck the bone and caused intense pain. The men often died of this pain before help arrived. When they were rescued the surgeons at once gave them morphine. A few hours later the injection was probably repeated. Then the drug was given less frequently, but in many cases it was not discontinued entirely while the man was in the hospital. A Red Cross surgeon at a meeting of the New York County Medical Society stated that he had been responsible for producing the morphine habit in thousands of soldiers, and that every physician at the front had done the same. By such a simple method as palming all this might have been prevented.

If we are going to have universal military and naval training, an essential part of that training should be the instruction of the prospective soldiers and sailors in the art of relieving their own pain; and in the event of war every one who goes to the front, in whatever capacity, from the generals and admirals down to the ambulance drivers, should understand palming. Everyone in the war zone, no matter how far behind the lines, may need this knowledge to relieve his own pain, and everyone may need it to relieve the pain of others.

CHAPTER XXXI

LETTERS FROM PATIENTS

The following letters have been selected almost at random from the author's mail-bag, and are only specimens of many more that are equally interesting. They are published: because it was felt that the personal stories of patients, told in their own language, might be more interesting and helpful to many readers than the more formal presentation of the facts in the preceding chapters.

ARMY OFFICER CURES HIMSELF

AS noted in the chapter on *What Glasses Do to Us*, the sight always improves when glasses are discarded, though this improvement may be so slight as not to be noticed. In a few unusual cases the patients, when freed from the handicap of a condition which compels them to keep their eyes continually under a strain, find out, in some way, how to avoid strain, and thus regain a greater or less degree of their normal visual power. The writer of the following letter was able, without any help from anyone, to discover and put into practice the main principles presented in this book, and thus became able to read without his glasses. He is an engineer, and at the time the letter was written was fifty-one years of age. He had worn glasses since 1896, first for astigmatism, getting stronger ones every couple of years, and then for astigmatism and presbyopia. At one time he asked his oculist and several opticians if the eyes could not be strengthened by exercises, so as to

Glasses At The Front 291

make glasses unnecessary, but they said: "No. Once started on glasses you must keep to them." When the war broke out he was very nearly disqualified for service in the Expeditionary Forces by his eyes, but managed to pass the required tests, after which he was ordered abroad as an officer in the Gas Service. While there he saw in the *Literary Digest* of May 2, 1918, a reference to my method of curing defective eyesight without glasses, and on May 11 he wrote to me in part as follows:

"At the front I found glasses a horrible nuisance, and they could not be worn with gas masks. After I had been about six months abroad I asked an officer of the Medical Corps about going without glasses. He said I was right in my ideas and told me to try it. The first week was awful, but I persisted and only wore glasses for reading and writing. I stopped smoking at the same time to make it easier on my nerves.

"I brought to France two pairs of bow spectacles and two extra lenses for repairs. I have just removed the extra piece for near vision from these extra lenses and had them mounted as pince-nez, with shur-on mounts, to use for reading and writing, so that the only glasses I now use are for astigmatism, the age lens being off. Three months ago I could not read ordinary head-line type in newspapers without glasses.

To-day, with a good light, I can read ordinary book type, held at a distance of eighteen inches from my eyes. Since the first week in February, when I discarded my glasses, I have had no headaches, stomach trouble, or dizziness, and am in good health generally. My eyes are coming back, and I believe it is due to sticking it out. I ride considerably in automobiles and trams, and somehow

292 Letters From Patients

the idea has crept into my mind that after every trip my eyes are stronger. This, I think, is due to the rapid changing of focus in viewing scenery going by so fast. Other men have tried this plan on my advice, but gave it up after two or three days. Yet, from what they say, I believe they were not so uncomfortable as I was for a week or ten days. I believe most people wear glasses because they 'coddle' their eyes."

The patient was right in thinking that the motor and tram rides improved his sight. The rapid motion compelled rapid shifting.

A TEACHER S EXPERIENCES

It has frequently been pointed out in this book that imperfect vision is always associated with an abnormal state of the mind, and that when the vision improves the mental faculties improve also, to a greater or less degree. The following letter is a striking illustration of this fact. The writer, a teacher forty years of age, was first treated on March 28, 1919. She was wearing the following glasses: right eye, convex 0.75D.S. with convex 4.00D.C., 105 deg.; left eye, convex 0.75D.S. with convex 3.50D.C., 105 deg. On June 9, 1919, she wrote:

"I will tell you about my eyes, but first let me tell you other things. You were the first to unfold your theories to me, and I found them good immediately - that is, I was favorably impressed from the start. I did not take up the cure because other people recommended it, but because I was convinced: first, that you believed in your discovery yourself; second, that your theory of the cause of eye trouble was true. I don't know how I knew these two things, but I did. After a little conversation with you, you and your discovery both seemed to me to bear

Enjoys Her Sight 293

the ear-marks of the genuine article. As to the success of the method with myself I had a little doubt. You might cure others, but you might not be able to cure me. However, I took the plunge, and it has made a great change in me and my life.

"To begin with, I enjoy my sight. I love to look at things, to examine them in a leisurely, thorough way, much as a child examines things. I never realized it at the time, but it was irksome for me to look at

things when I was wearing glasses, and I did as little of it as possible. The other day, going down on the Sandy Hook boat, I enjoyed a most wonderful sky without that hateful barrier of misted glasses, - and I am positive I distinguished delicate shades of color that I never would have been able to see, even with clear glasses. Things seem to me now to have more form, more reality, than when I wore glasses. Looking into the mirror you see a solid representation on a flat surface, and the flat glass can't show you anything really solid. My eyeglasses, of course, never gave me this impression, but one curiously like it. I can see so clearly without them that it is like looking around corners without changing the position. I feel that I can almost do it.

"I very seldom have occasion to palm. Once in a great while I feel the necessity of it. The same with remembering a period. Nothing else is ever necessary. I seldom think of my eyes, but at times it is borne in upon me how much I do use and enjoy using them.

"My nerves are much better. I am more equable, have more poise, I am less shy. I never used to show that I was shy, or lacked confidence. I used to go ahead and what was required, if not without hesitation; but it was hard. Now I find it easy. Glasses, or poor sight

294 Letters From Patients

rather, made me self-conscious. It certainly is a great defect, and one people are sensitive to without realizing it. I mean the poor sight and the necessity for wearing glasses. I put on a pair of glasses the other day just for an experiment, and I found that they magnified things. My skin looked as if under a magnifying glass. Things seemed too near. The articles on my chiffonier looked so close I felt like pushing them away from me. The glasses I especially wanted to push away. They brought irritation at once. I took them off and felt peaceful. Things looked normal.

"From the beginning of the treatment I could use my eyes pretty well, but they used to tire. I remember making a large Liberty Loan poster two weeks after I took off my glasses, and I was amazed to find I could make the whole layout almost perfectly without a ruler just as well as with my glasses. When I came to true it up with the ruler I found only the last row of letters a bit out of line at the very end. I couldn't have done better with glasses. However this wasn't fine work. About the same time I sewed a hem at night in a black dress, using a fine needle. I suffered a little for this but not much. I used to practice my exercises at that time, and palm faithfully. Now I don't have to practice, or palm; I feel no discomfort, and I am absolutely unsparing in my use of my eyes. I do everything I want to with them. I shirk nothing, pass up no opportunity of using them. From the first I did all my school work, read every notice, wrote all that was necessary, neglected nothing.

"Now to sum up the school end of it: I used to get headaches at the end of the month from adding columns of figures necessary to reports, etc. Now I do not get them. I used to get flustered when people came into

my room. Now I do not; I welcome them. It is a pleasant change to feel this way. And - I suppose this is most important really, though I think of it last - I teach better. I know how to get at the mind and how to make the children see things in perspective. I gave a lesson on the horizontal cylinder recently, which, you know, is not a thrillingly interesting subject, and it was a remarkable lesson in its results and in the grip it got on every girl in the room, stupid or bright. What you have taught me makes me use the memory and imagination more, especially the latter, in teaching.

"To sum up the effect of being cured upon my own mind: I am more direct, more definite, less diffused, less vague. In short, I am conscious of being better centered. It is central fixation of the mind. I saw this in your latest paper, but I realized it long ago and knew what to call it."

A MENTAL TRANSITION

A man of forty-four who had worn glasses since the age of twenty was first seen on October 8, 1917, when he was suffering, not only from very imperfect sight, but from headache and discomfort. He was wearing for the right eye concave 5.00D.S. with concave 0.50D.C., 180 degrees, and for the left concave 2.50D.S. with concave 1.50D.C., 180 degrees. As his visits were not very frequent and he often went back to his glasses, his progress was slow. But his pain and discomfort were relieved very quickly, and almost from the beginning he had flashes of greatly improved and even of normal vision. This encouraged him to continue, and his progress,

296 Letters From Patients

dition has improved as much as his sight. His wife was particularly impressed with the latter effect, and in December, 1919, she wrote:

"I have become very much interested in the thought of renewing my youth by becoming like a little child. The idea of the mental transition is not unfamiliar, but that this mental, or I should say spiritual, transition should produce a physical effect, which would lead to seeing clearly, is a sort of miracle very possible indeed, I should suppose, to those who have faith.

"In my husband's case, certainly, some such miracle was wrought; for not only was he able to lay aside his spectacles after many years constant use, and to see to read in almost any light, but I particularly noticed his serenity of mind after treatments. In this serenity he seemed able to do a great deal of work efficiently, and not under the high nervous pressure whose after-effect is the devastating scattering of forces.

"It did not occur to me for a long time that perhaps your treatment was quieting his nerves. But I think

now that the quiet periods of relaxation, two or three times a day, during which he practiced with the letter card, must have had a very beneficial effect. He is so enthusiastic by nature, and his nerves are so easily stimulated, that for years he used to overdo periodically. Of course, his greatly improved eyesight and the relief from the former strain must have been a large factor in this improvement. But I am inclined to think that the intervals of quiet and peace were wonderfully beneficial. and why shouldn't they be? We are living on stimulants, physical stimulants, mental stimulants of all kinds. The minute these stop we feel we are merely existing, and yet, if we retain any of the normality of our youth, do you

Relaxation Versus Glasses 297

not think that we respond very happily to natural simple things ?"

RELIEF AFTER TWENTY-FIVE YEARS

While many persons are benefited by the accepted methods of treating defects of vision, there is a minority of cases, known to every eye specialist, which gets little or no help from them. These patients sometimes give up the search for relief in despair, and sometimes continue it with surprising pertinacity, never being able to abandon the belief, in spite of the testimony of experience, that somewhere in the world there must be some one with sufficient skill to fit them with the right glasses. The rapidity with which these patients respond to treatment by relaxation is often very dramatic, and affords a startling illustration of the superiority of this method to treatment by glasses and muscle-cutting. In the following case relaxation did in twenty-four hours what the old methods, as practiced by a succession of eminent specialists, could not do in twenty-five years.

The patient was a man of forty-nine, and his imperfect sight was accompanied by continual pain and misery, culminating twenty years before I saw him, in a complete nervous breakdown. As he was a writer, dependent upon his pen for a living, his condition was a serious economic handicap, and he consulted many specialists in the vain hope of obtaining relief. Glasses did little,- either to improve his sight, or to relieve his discomfort, and the eye specialists talked vaguely about disease of the optic nerve and brain as a possible cause of his troubles. The nerve specialists, however, were unable to do anything to relieve him. One specialist diagnosed his case as muscular, and gave him prisms, which helped him a little.

298 Letters From Patients

Later, the same specialist, finding that all of the apparent muscular trouble was not corrected by glasses, cut the external muscles of both eyes. This also brought some relief, but not much. At the age of twenty-nine the patient suffered the nervous breakdown already mentioned. For this he was treated unsuccessfully by various specialists, and for nine years he was compelled to live out of doors. This life,

although it benefited him, failed to restore his health, and when he came to me on September 15, 1919, he was still suffering from neurasthenia. His distant vision was less than 20/40, and could not be improved by glasses. He was able to read with glasses, but could not do so without discomfort. I could find no symptom of disease of the brain or of the interior of the eye. When he tried to palm he saw grey and yellow instead of black; but he was able to rest his eyes simply by closing them, and by this means alone he became able, in twenty-four hours, to read diamond type and to make out most of the letters on the twenty line of the test card at twenty feet. At the same time his discomfort was materially relieved. He was under treatment for about six weeks, and on October 25 he wrote as follows:

"I saw you last on October 6, and at the end of the week, the 11th, I started off on a ten-day motor trip as one of the officials of the Cavalry Endurance Test for horses. The last touch of eyestrain which affected me nervously at all I experienced on the 8th and 9th. On the trip, though I averaged but five hours' sleep, rode all day in an open motor without goggles and wrote reports at night by bad lights, I had no trouble. After the third day the universal slow swing seemed to establish itself, and I have never had a moment's discomfort since. I stood fatigue and excitement better than I have ever

Out Of The Woods 299

done, and went with less sleep. My practicing on the trip was necessarily somewhat curtailed, yet there was noticeable improvement in my vision. Since returning I have spent a couple of hours a day in practice, and have at the same time done a lot of writing.

"Yesterday, the 24th, I made a test with diamond type, and found that after twenty minutes' practice I could get the lines distinct, and make out the capital letters and bits of the text at a scant three inches. At seven I could read it readily, though I could not see it perfectly. This was by an average daylight - no sun. In a good daylight I can read the newspaper almost perfectly at a normal reading distance, say fifteen inches.

"I feel now that I am really out of the woods. I have done night work without suffering for it, a thing I have not done in twenty-five years, and I have worked steadily for more hours than I have been able to work at a time since my breakdown in 1899, all without sense of strain or nervous fatigue. You can imagine my gratitude to you. Not only for my own sake, but for yours, I shall leave no stone unturned to make the cure complete and get back the child eyes which seem perfectly possible in the light of the progress I have made in eight weeks."

SEEKING A MYOPIA CURE

In spite of the emphasis with which the medical profession denies the possibility of curing errors of refraction, there are many lay persons who refuse to believe that they are incurable. The author of the following statement represents a considerable class, and was remarkable only in the persistency with

which he searched for relief. He was first seen on June 27, 1919, at which time he was thirty-two years of age. He was wearing

300 Letters From Patients

concave 2.50D.S. for each eye, and his vision in each eye was 20/100 - . After he had obtained almost normal vision he wrote the following account of his experiences for *Better Eyesight*:

"When the *Lusitania* was sunk I knew that the United States was going to get into trouble, and I wanted to be in a position to join the Army. But I was suffering from a high degree of myopia, and I knew they wouldn't take me with glasses. Later on they took almost anyone who wasn't blind, but at that time I couldn't possibly have measured up to the standard. So I began to look about for a cure. I tried osteopathy, but didn't go very far with it. I asked the optician who had been fitting me with glasses for advice, - but he said that myopia was incurable. I dismissed the matter for a time, but I didn't stop thinking about it. I am a farmer, and I knew from the experience of outdoor life that health is the normal condition of living beings. I knew that when health is lost it can often be regained. I knew that when I first tried to lift a barrel of apples onto a wagon I could not do so, but that after a little practice I became able to do it easily, and I did not see why, if one part of the body could be strengthened by exercise, others could not be strengthened also. I could remember a time when I was not myopic, and it seemed to me that if a normal eye could become myopic, it ought to be possible for a myopic eye to regain normality. After a while I went back to the optician and told him that I was convinced that there must be some cure for my condition. He replied that this was quite impossible, as everyone knew that myopia was incurable. The assurance with which he made this statement had an effect upon me quite the opposite of what he intended, for when he said that the cure of

It Ought To Be E Possible 301

myopia was impossible I knew that it was not, and I resolved never to give up the search for a cure until I found it. Shortly after I had the good fortune to hear of Dr. Bates, and lost no time in going to see him. At the first visit I was able, just by closing and resting my eyes, to improve my sight considerably for the Snellen test card, and after a few months of intermittent treatment I became able to read 20/10 - in flashes. I am still improving, and when I can see a little better I mean to go back to that optician and tell him what I think of his ophthalmological learning."

FACTS VERSUS THEORIES

Reading fine print is commonly supposed to be an extremely dangerous practice, and reading print of any kind upon a moving vehicle is thought to be even worse. Looking away to the distance, however, and not seeing anything in particular is believed to be very beneficial to the eyes. In the light of these

superstitions the facts contained in the following letter are particularly interesting:

"On reaching home Monday morning I was surprised and pleased at the comments of my family regarding the appearance of my eyes. They all thought they looked so much brighter and rested, and that after two days of railroading. I didn't spare my eyes in the least on the way home. I read magazines and newspapers, looked at the scenery; in fact, used my eyes all the time. My sight for the near-point is splendid. Can read for hours without tiring my eyes. I went downtown to-day and my eyes were very tired when I got home. The fine print on the card [diamond typed] helps me so much I would like to have your little Bible [a photographic re-

302 Letters Prom Patients

duction of the Bible with type much smaller than diamond]. I'm sure the very fine print has-a soothing effect on one's eyes, regardless of what my previous ideas on the subject were."

It will be observed that the eyes of this patient were not tired by her two days railroad journey, during which she read constantly; they were not tired by hours of reading after her return; they were rested by reading extremely fine print; but they were very much tired by a trip downtown during which they were not called upon to focus upon small objects. Later a leaf from the Bible was sent to her, and she wrote:

"The effect even of the first effort to read it was wonderful. If you will believe it, I haven't been troubled having my eyes feel 'crossed' since, and while my actual vision does not seem to be any better, my eyes feel a great deal better."

CURED WITHOUT PERSONAL ASSISTANCE

I am constantly hearing of patients who have been able to improve their sight by the aid of information contained in my publications, without personal assistance. The writer of the following letter, a physician, is a remarkable example of these cases, as he was able not only to cure himself, but to relieve some very serious cases of defective vision among his patients.

"I first tried central fixation on myself and had marvelous results. I threw away my glasses and can now see better than I have ever done. I read very fine type (smaller than newspaper type) at a distance of six inches from the eyes, and can run it out at full arm's length and still read it without blurring the type. "I have instructed some of my patients in your

Cataract Relieved 303

methods, and all are getting results. One case who has a partial cataract of the left eye could not see anything on the Snellen test card at twenty feet, and could see the letters only faintly at ten feet. Now she, can read 20/10 with both eyes together, and also with each eye separately; but the left eye seems, as she

says, to be looking through a little fog. I could cite many other cases that have been benefited by central fixation, but this one is the most interesting to me."

CHAPTER XXXII

REASON AND AUTHORITY

SOME ONE - perhaps it was Bacon - has said: "You cannot by reasoning correct a man of ill opinion which by reasoning he never acquired." He might have gone a step further and stated that neither by reasoning, nor by actual demonstration of the facts, can you convince some people that an opinion which they have accepted on authority is wrong.

A man whose name I do not care to mention, a professor of ophthalmology, and a writer of books well known in this country and in Europe, saw me perform the experiment illustrated on page 40, an experiment which, according to others who witnessed it, demonstrates beyond any possibility of error that the lens is not a factor in accommodation. At each step of the operation he testified to the facts; yet at the conclusion he preferred to discredit the evidence of his senses rather than accept the only conclusion that these facts admitted.

First he examined the eye of the animal to be experimented upon, with the retinoscope, and found it normal, and the fact was written down. Then the eye was stimulated with electricity, and he testified that it accommodated. This was also written down. I now divided the superior oblique muscle, and the eye was again stimulated with electricity. The doctor observed the eye with the retinoscope when this was being done and said: "You failed to produce accommodation." This fact, too, was written down. The doctor now used the electrode himself, but again failed to observe accommodation, and

304

Discredited His Own Observations 305

these facts were written down. I now sewed the cut ends of the muscle together, and once more stimulated the eye with electricity. The doctor said, "Now you have succeeded in producing accommodation," and this was written down. I now asked:

"Do you think that superior oblique had anything to do with producing accommodation ?"

"Certainly not," he replied.

"Why ?" I asked.

"Well," he said, "I have only the testimony of the retinoscope; I am getting on in years, and I don't feel that confidence in my ability to use the retinoscope that I once had. I would rather you wouldn't quote me on this."

While the operation was in progress, however, he gave no indication whatever of doubting his ability to use the retinoscope. He was very positive, in fact, that I had failed to produce accommodation after the cutting of the oblique muscle, and his tone suggested that he considered the failure ignominious. It was only after he found himself in a logical trap, with no way out except by discrediting his own observations, that he appeared to have any doubts as to their value.

Patients whom I have cured of various errors of refraction have frequently returned to specialists who had prescribed glasses for them, and, by reading fine print and the Snellen test card with normal vision, have demonstrated the fact that they were cured, without in any way shaking the faith of these practitioners in the doctrine that such cures are impossible.

The patient with progressive myopia whose case was mentioned in Chapter XV returned after her cure to the specialist who had prescribed her glasses, and who had said not only that there was no hope of improvement, but

306 Reason And Authority

that the condition would probably progress until it ended in blindness, to tell him the good news which, as an old friend of her family, she felt he had a right to hear. But while he was unable to deny that her vision was, in fact, normal without glasses, he said it was impossible that she should have been cured of myopia, because myopia was incurable. How he reconciled this statement with his former patient's condition he was unable to make clear to her.

A lady with compound myopic astigmatism suffered from almost constant headaches which were very much worse when she took her glasses off, The theatre and the movies caused her so much discomfort that she feared to indulge in these recreations. She was told to take off her glasses and advised, among other things, to go to the movies; to look first at the corner of the screen, then off to the dark, then back to the screen a little nearer to the center, and so forth. She did so, and soon became able to look directly at the pictures without discomfort. After that nothing troubled her. One day she called on her former ophthalmological adviser, in the company of a friend who wanted to have her glasses changed, and told him of her cure. The facts seemed to make no impression on him whatever. He only laughed and said, "I guess Dr. Bates is more popular with you than I am."

Sometimes patients themselves, after they are cured, allow themselves to be convinced that it was impossible that such a thing could have happened, and go back to their glasses. This happened in the case of a patient already mentioned in the chapter on *Presbyopia*, who was cured in fifteen minutes by the aid of his imagination. He was very grateful for a time, and then he began to talk to eye specialists whom he knew and straightway grew skeptical as to the value of what I had done for him.

One day I met him at the home of a mutual friend, and in the presence of a number of other people he accused me of having hypnotized him, adding that to hypnotize a patient without his knowledge or consent was to do him a grievous wrong. Some of the listeners protested that whether I had hypnotized him or not, I had not only done him no harm but had greatly benefited him, and he ought to forgive me. He was unable, however, to take this view of the matter. Later he called on a prominent eye specialist who told him that the presbyopia and astigmatism from which he had suffered were incurable, and that if he persisted in going without his glasses he might do himself great harm. The fact that his sight was perfect for the distance and the near-point without glasses had no effect upon the specialist, and the patient allowed himself to be frightened into disregarding it also. He went back to his glasses, and so far as I know has been wearing them ever since. The story obtained wide publicity, for the man had a large circle of friends and acquaintances; and if I had destroyed his sight I could scarcely have suffered more than I did for curing him.

Fifteen or twenty years ago the specialist mentioned in the foregoing story read a paper on cataract at a meeting of the ophthalmological section of the American Medical Association in Atlantic City, and asserted that anyone who said that cataract could be cured without the knife was a quack. At that time I was assistant surgeon at the New York Eye and Ear Infirmary, and it happened that I had been collecting statistics of the spontaneous cure of cataract at the request of the executive surgeon of this institution, Dr. Henry G. Noyes, Professor of Ophthalmology at the Bellevue Hospital Medical School. As a result of my inquiry I had secured records of a large num-

308 Reason And Authority

ber of cases which had recovered, not only without the knife, but without any treatment at all I also had records of cases which I had sent to Dr. James E. Kelly of New York and which he had cured, largely by hygienic methods. Dr. Kelly is not a quack, and at that time was Professor of Anatomy in the New York Post Graduate Medical School and Hospital and attending surgeon to a large city hospital. In the five minutes allotted to those who wished to discuss the paper, I was able to tell the audience enough about these cases to make them want to hear more. My time was, therefore, extended, first to half an hour and then to an hour. Later both Dr. Kelly and myself received many letters from men in different parts of the country who had tried his treatment with success. The man who wrote the paper had blundered, but he did not lose any prestige because of my attack, with facts, upon his theories. He is still a prominent and honored ophthalmologist, and in his latest book he gives no hint of having ever heard of any successful method of treating cataract other than by operation. He was not convinced by my record of spontaneous cures, nor by Dr. Kelly's record of cures by treatment; and while a few men were sufficiently impressed to try the treatment recommended, and while they obtained satisfactory results, the facts made no impression upon the profession as a whole, and did not modify the teaching of the schools. That spontaneous cures of cataract do sometimes occur cannot be denied; but they are supposed to be very rare, and any one who suggests that the condition can be cured by treatment still exposes himself to the suspicion of being a quack.

Between 1886 and 1891 I was a lecturer at the Post Graduate Hospital and Medical School. The head of the institution was Dr. D. B. St. John Roosa. He was

Man Not A Reasoning Being 309

the author of many books, and was honored and respected by the whole medical profession. At the school they had got the habit of putting glasses on the nearsighted doctors, and I had got the habit of curing them without glasses. It was naturally annoying to a man who had put glasses on a student to have him appear at a lecture without them and say that Dr. Bates had cured him. Dr. Roosa found it particularly annoying, and the trouble reached a climax one evening at the annual banquet of the faculty when, in the presence of one hundred and fifty doctors, he suddenly poured out the vials of his wrath upon-my head. He said that I was injuring the reputation of the Post Graduate by claiming to cure myopia. Every one knew that Donders said it was incurable, and I had no right to claim that I knew more than Donders. I reminded him that some of the men I had cured had been fitted with glasses by himself. He replied that if he had said they had myopia he had made a mistake. I suggested further investigation. "Fit some more doctors with glasses for myopia," I said, "and I will cure them. It is easy for you to examine them afterwards and see if the cure is genuine." This method did not appeal to him, however. He repeated that it was impossible to cure myopia, and to prove that it was impossible he expelled me from the Post Graduate, even the privilege of resignation being denied to me.

The fact is that, except in rare cases, man is not a reasoning being. He is dominated by authority, and when the facts are not in accord with the view imposed by authority, so much the worse for the facts. They may, and indeed must, win in the long run; but in the meantime the world gropes needlessly in darkness and endures much suffering that might have been avoided.

Your Glasses and Your Eyes Twenty Lessons

Written in short and simple language

Ten Lessons on Your Glasses Ten Lessons on Your Eyes

By
Dr. Jacob Raphaelson, O.D., *Retired*

Copyright © 1956 by Jacob Raphaelson, O.D.

First published in 1956 by Research Foundation for Prevention of Myopia.

Hypertext version edited by Alex Eulenberg; last revision February 21, 2003.

We are confronted with compulsory unnatural use of our eyes. It is about time that our educators, legislators, medical men and the general public acquire some basic and practical knowledge about spectacles and glasses.

This book is written for the public
In the language of the public

Preface

For more than fifty-five years the author of this book has been doing independent optical research on the relationship of vision, spectacles and health. He has made some discoveries and has come to certain conclusions which are unknown to the medical and optical professions. He has developed a new approach to the fitting and wearing of spectacles and glasses. It follows the basic principles of optics; it

does not follow the path as practiced, at present, by the optical professions.

The author believes that, in regard to the relationship of spectacles, vision and health, the medical and optical professions are in a state of confusion and on the wrong track. He has written this book to clarify and simplify the matter and to uncover the mystery about the fitting and wearing of spectacles and glasses.

Lesson 1

Spectacles and Glasses

Spectacles and Glasses are two names for the same thing. They are a pair of lenses mounted in a frame. The lenses are, mostly, transparent glass with surfaces ground or molded to a certain curvature. This curvature gives optical power to the lenses. It bends rays of light passing through the lenses and brings them to a focus. The purpose of the frame is to hold the lenses firmly and steadily in front of the eyes.

Formerly they were called spectacles. They were small lenses mounted in a metal rim with side or ear temples. They were used, mainly, by older persons to read smaller print. Later, when some spectacles were made without temples they were called Eye-glasses. In the early 19th century, when younger adults began to wear spectacles constantly, a nose piece was developed which held them firmly on the nose. These were called "Nose-glasses." In recent years, when plastic frames became popular and nose-glasses almost disappeared, the name glasses came into popular use.

Glasses, at present, is the popular name for spectacles. Glasses is a meaningless word; it has nothing to differentiate it from beer-glasses or colored-glasses. The dictionary will not help us because the name "Glasses" is not to be found in the old or new dictionaries. The lack of knowledge about spectacles is widespread. It includes not only the ordinary person but also our educators, our legislators, and most of the medical profession. A proper name for spectacles would be Focus-glasses.

Formerly, when they were called spectacles it was believed that they were, more or less, spectacular and fictitious. Now, they are believed to be mystic, some mystery in the glass or about the glass that makes you see better or worse. Lately, I asked a medical doctor, (a pathology professor in a large eastern medical college): "What is it in glasses that makes you see better or worse?" First he tried to give me a meaningless answer. When I insisted on a clear answer, he said: "It is the molecular structure of the glass." His answer proved his confusion about spectacles and glasses.

It is important that we know and understand that it is the curvature in the lenses that gives it the optical power. It is the curvature in the spectacles or glasses that changes the focus in our eyes.

Lesson 2

The Focus In Glasses

A focus means a point, any central point. In optics, it means the point where rays of light meet after being bent (refracted) by a lens. It also means the line or distance from the lens to the point. It also means many points forming an image or picture. In taking pictures with a camera, "to focus" means obtaining a sharp and clear picture.

In taking pictures, in order to get a clear picture, the photographer has to adjust the camera according to the distance of the person from the camera -- everyone knows that. The eye, which is physically a miniature camera, also has to make adjustments for different distances -- no one seems to know that.

Lenses, which are curved glass, will bend or refract rays of light and heat towards the thicker part of the lenses. If it is a convex lens, which is thicker in the center, light rays will bend towards the center and come to a point or focus some distance from the lens. If it is a strong lens, it will come to a point near the lens. If it is a weak lens, it will come to a focus farther away.

The lenses in your spectacles or glasses affect and change the course of light rays entering your eyes. They affect and change the focus in your eyes. If it is a convex lens, the focus will be closer -- if a concave lens, the focus will be farther. A neutral lens will not affect the focus, and will not make you see better or worse. A neutral lens is one that is neither convex or concave. It is one that has the same thickness over the whole surface of the lens. It is called plano lens.

Spectacles or glasses that affect our vision in any way are focus-glasses. They have optical power to change the focus in our eyes. They have curvature, either convex or concave.

Lesson 3

The Curvature in Glasses

A curve means a bend -- a bend means a curve. Most of us are familiar with curves or bends on the road. There are straight roads and curved roads. There are short curves, and long curves that are hardly noticeable. A curve is part of a circle, it is also part of a sphere, and it is also part of a cylinder. In optics, a curve is called a curvature.

It is the curvature in your eyes that makes them focus and produce a clear picture. It is the curvature in the lenses that gives them the optical power to focus or to change the focus in your eyes -- it is this curvature and nothing else. There are no molecular changes in the glasses, there are no other physical or chemical changes. The differences in lenses are differences in curvature. A higher curvature is a higher power lens. A lower curvature is a weaker power lens.

When you go to an oculist or optometrist and he prescribes a pair of glasses, it is curvature that he prescribes, one diopter or a half a diopter of curvature in the lenses. He may prescribe spherical or cylindrical curvature. He may combine them both. He may prescribe a little spherical and a little curvature in each lens.

Lenses, to have optical power, must have either an elevated surface which is a convex curvature, or a depressed surface which is a concave curvature. If a lens has an elevation on one side and a depression on the other side it loses its optical power. If the depression is as much as the elevation it loses all optical power. It becomes a neutral lens. It is the remainder of curvature that gives the optical power. The curvature on lenses is measured by the diopter. The unit is one diopter (symbol 1.00d.).

Note

The optical curvatures of lenses and of our eyes are relative curvatures. It is similar to relative humidity.

[Contents](#) | [Lesson 2](#) | [Lesson 4](#)

Lesson 4

The Diopter Unit

Formerly, lenses were measured by the focus in inches. If a lens was strong enough to focus at one inch, it was called a one inch lens. If it focused at ten inches, it was called a ten inch lens. At forty inches, it was a forty inch lens. Now, instead of measuring the length of the focus we measure the curvature which makes the focus. A forty inch focus was adopted as the unit measure of curvature. It was given the name Diopter. One diopter equals a 40 inch focus lens.

The Diopter measures the curvature power of lenses similar to the dollar which measures the purchasing power of money. Both are shortened by the initial D. or d. Both are added and subtracted, both are divided in halves and quarters. The unit of both is "one, period, double zero (1.00). One and a half is written 1.50, one and one-quarter is written 1.25.

The Diopter is added and subtracted the same as the dollar. If you have a plus 6.00 curvature on one side of the lens and a minus 5.00 curvature on the other side, it is a plus 1.00 lens. if you have a plus 6.00 on one side and a minus 7.00 on the other side, it is a minus 1.00 lens. The plus curvature lenses add curvature to your eyes. The minus curvature lenses subtract and reduce the curvature of your eyes.

If a lens is ground or molded with a plus 6.00 curvature on one side of the lens and a minus 6.00 on the other side, the curvatures neutralize each other. It becomes a neutral lens. If lenses are ground or molded with plus curvatures on one side and with identical minus curvatures on the other side, they are called plano lenses. They have no optical power. The proper name for them should be "Neutral lenses" and "Neutral glasses."

Lesson 5

Colored Glasses

Colored glasses are sold in nearly all drugstores, department, variety, five-and-ten, and many other stores. They have become popular. In fact, they have become too popular. There are many who are wearing colored glasses who would do better if they wore focus-glasses instead (see "Color vs. Focus in Glasses", link forthcoming). The purpose of color is to diminish the brightness of sunlight. They are called sun-glasses.

Sun-glasses are made in a variety of colors and shades. In most cases, it is the customer who picks the color or shade. So far, there is no special color which is generally claimed, by the public or the optical profession, to be the best color. In fact, I saw a government booklet, a few years ago, which stated that, after some years of research, they were still unable to determine which color would be best.

Colored glasses, sold in stores, have no optical power, they do not change or affect the focus. They are neutral glasses. The same is true of goggles, which have no color. Goggles protect the eyes from dust or cinders. many goggle-wearers also would do better if they wore focus-glasses (see "Dust and Focus", link forthcoming). In many cases, oculists and optometrists prescribe a shade of color in the focus-glasses. Color can be added to focus and focus can be added to colored glasses.

Colored glasses or goggles are made with flat lenses and with curved lenses. Most colored glasses have a plus 6.00 curvature on the outside surface of the lenses and a minus 6.00 curvature on the inside surface. Some colored glasses and goggles have as high as a plus 10.00 curvature on the outside and a minus 10.00 on the inside.

Colored glasses are popular. Plus focus-glasses are unwelcome -- this is because the benefits of colored glasses are apparent and visible, while the benefits of plus focus-glasses, in most cases, are hidden and invisible.

Lesson 6

FOCUS GLASSES (new term)

Focus-glasses are those which affect and change the focus in our eyes. About ninety-nine per cent of glasses prescribed by oculists are focus-glasses. The lenses have either a plus (convex) curvature which shortens the focus, or a minus (concave) curvature which lengthens the focus. The lenses are either plus, which add curvature to your eyes, or minus, which subtract and take away curvature from your eyes.

It is important, it is very important, that we recognize and emphasize the difference between plus and minus lenses.

They are opposite to each other.
They neutralize each other.

Plus is like a hill	Minus is like a hollow
Plus stands for positive	Minus stands for negative
Plus magnifies	Minus reduces
Plus means convex	Minus means concave
Plus adds curvature	Minus subtracts curvature
Plus helps nearer seeing	Minus helps farther seeing

The lenses in opera glasses, camera lenses, magnifiers and microscopes are all focus lenses. They all have plus (convex) curvatures which bend or refract light and heat rays which fall on their surfaces. They bend the rays towards an imaginary line from the optical center of the lens to the focus, which is some distance from the lens. This distance depends on the curvature of the lens. A little curvature will have the focus far away. More curvature will bring the focus nearer.

Colored glasses and goggles are not focus-glasses because they are either flat or neutral. Prism lenses are not focus lenses because they bend light rays into a line instead of a point or focus. Focus lenses are those which are either plus or minus.

Lesson 7

PLUS AND MINUS GLASSES

A FAR-SIGHTED LENS, A CONVEX LENS, A MAGNIFYING LENS, A POSITIVE LENS AND A PLUS LENS ARE DIFFERENT NAMES FOR THE SAME LENS.

It is called a far-sighted lens, because it is fitted to far-sighted eyes; a convex lens because it has an elevated surface, and is thicker in the center and thinner at the edges; a magnifying lens because it magnifies things and makes them look larger; a positive lens because it bends rays of light inwards and brings them to focus; a plus lens because it adds curvature to your eyes.

A NEAR-SIGHTED LENS, A CONCAVE LENS, A REDUCING LENS, A NEGATIVE LENS AND A MINUS LENS ARE DIFFERENT NAMES FOR THE SAME LENS.

It is called a near-sighted lens because it is fitted to near-sighted eyes; a concave lens because it has a depressed surface and is thinner at the center and thicker at the edges; a reducing lens because it reduces and makes things look smaller; a negative lens because it bends rays of light outwards and spreads them away from the focus; and a minus lens because it subtracts and lessens the curvatures of your eyes.

Plus and minus lenses are each subdivided into spherical lenses and cylinder lenses. They are designated as plus spherical and minus spherical lenses. They are also designated as plus cylinder and minus cylinder lenses. The spherical and cylinder curvatures are often ground on one lens. Formerly they used to grind the sphere on one side and the cylinder on the other side. Now, both are ground on one surface of the lens. It is a compound (toric) curvature. It is similar to an egg-shaped curvature.

The eyes, being spherical in shape, mostly, need and require spherical lenses.

[Contents](#) | [Lesson 6](#) | [Lesson 8](#)

Lesson 8

SPHERICAL LENSES

The main division of lenses is plus and minus. Each is subdivided into spherical and cylinder lenses. They are plus sphere or plus cylinder, and minus sphere or minus cylinder lenses. Sph. stands for spherical and Cl. stands for cylinder. Most often the sign for spherical is omitted. It is assumed to be aspherical lens, unless it is marked cylinder and the axis is given. Opera glasses, camera and magnifying lenses, microscope and telescope lenses are understood to be spherical lenses.

A sphere is a round body like a ball or globe. It is round equally in all directions. Spherical curvature means that the curvature is identical in all directions. Spherical lenses mean that the surfaces of the lenses are spherical in shape. A spherical lens is really a piece of the outer portion of a sphere. A spherical plus curvature is ground on the surface of the lens with a minus tool. A minus curvature is ground with a plus tool.

When you get a prescription for a pair of glasses, the symbol of plus (+) or minus (-) is always designated, but seldom the sphere. It is assumed to be spherical. Thus a prescription for a 3/4 diopter plus lens will be +0.75, a minus 3/4 of a diopter will read -0.75; likewise +1.50 or -1.50, +3.00 and -3.00.

Spherical lenses can be correctly made in mass production. On a small comparative scale, they are now being made in mass production on precise automatic machines. They are being made to be sold ready-to-wear in frames, and also for the greater portion of spherical lenses, which are prescribed by oculists and optometrists.

Mass-produced spherical lenses can be more precise and less subject to mistakes and imperfections than the spherical lenses that are being ground in small shops. Mass-produced lenses can be, and are, produced cheaply.

[Contents](#) | [Lesson 7](#) | [Lesson 9](#)

Lesson 9

CYLINDER LENSES

A cylinder is a body that is round like a circle and has curvature in one direction and is flat or neutral in the opposite direction. Thus a broomstick or a water pipe is like a cylinder. The round body of a bottle and tin can are good illustrations of cylinders.

The flat or neutral side of the cylinder is called the axis. The curvature is in the opposite direction of the axis. Thus, if a water pipe is set vertically, up and down, the axis is 90 degrees. If set horizontally, the axis would be 180 degrees. A cylinder lens is, in reality, a small piece of the outer portion of a cylinder.

Cylinder lenses also are either minus or plus. They have plus or minus curvature in one direction with the axis in the opposite direction. Thus, if a cylinder lens is set in your frame with the axis at 90 degrees, the curvature of the lens will be in the opposite direction. Cylinder lenses, like water pipes, are sometimes set at an angle. The axis is then given by degrees.

If a cylinder lens is prescribe, it must be designated as plus or minus and also the axis of the cylinder must be stated. Thus a cylinder prescription is written in symbol, +0.50 x 90, or -0.50 x 90. Likewise, +0.5. x 120, or -0.5. x 120, or any other given axis.

Many lenses are prescribed with both the sphere and the cylinder in the same lens. They are called compound lenses. They have a certain spherical curvature and a cylinder curvature added to the spherical. They are egg-shaped but not noticeably so. They are written as follows: plus 1.00 sph. combined with plus 0.50 cl. axis 90 -- in symbol it is +1.00==+0.50x90. They are written in many variations.

[Contents](#) | [Lesson 8](#) | [Lesson 10](#)

Lesson 10

READY-TO-WEAR GLASSES

Ready-to-wear glasses are plus spherical glasses. There are no minus lenses nor cylinder lenses in glasses that are made to sell ready-to-wear. But, the ready-to-wear glasses of past and present have no symbol that they are plus and no sign that they are spherical. They have tags on them, but the tags are confusing. Neither the seller nor the buyer knows what the tags mean. The tags give you both numbers; the old inch system and the diopter number. The tags are a left-over from olden times.

The tags have the diopter number plainly written. Only the symbol of plus is omitted. They seem like price numbers. In olden times they may have known better. If you disregard the inch number you can readily tell, in diopters, what strength each pair of glasses has. You would know what you are looking for.

Ready-to-wear glasses are plus and spherical. Therefore, they can do no harm to your eyes or vision. It is only minus lenses or cylinder lenses that may do you harm if fitted wrongly. The minus lenses can, mainly, be harmful if used for near seeing. The cylinder lenses can be harmful if too much cylinder is given, and if the axis is not set in the right position.

Plus spherical glasses are always beneficial for nearer vision. Also, they will do you no harm, rather they will do your eyes good if you wear them for distance, even when you can see better with the naked eyes. Plus spherical glasses relax and stretch your eyes. They give your eyes a posture similar to star-gazing. And the posture of star-gazing is what the eyes of civilized human beings need and what they do not have.

Ready-to-wear glasses can be had from one-quarter of a diopter up to five diopters--symbols 0.25 up to 5.00. The weaker numbers, 0.25 up to 1.25 can safely be used by children and adults up to the age of forty-five or older. They are a positive help in near-seeing and many benefits may be had by their use for distant seeing. The stronger numbers of glasses are, mainly, used by older persons for reading and other near work. Also, they are used by the higher grades of hyper-sighted eyes (see [Lesson 16](#)) which require stronger plus glasses.

Lesson 16

HYPER-SIGHTED EYES (new term)

"Hyper-sighted" eyes is a new term. It is a suitable term for "Hyper-opia," misnamed "far-sighted" eyes. Hyper-sighted eyes have too much curvature. Hyper-sighted eyes do not have enough curvature. The focus in near-sighted eyes is too short. The focus in hyper-sighted eyes is too long. It is too long because hyper-sighted eyes are deficient in curvature. *<More than 80 per cent of all persons have hyper-sighted eyes.*

Hyper-sighted eyes, when fully relaxed or flattened, are unable to see distant objects clearly without the assistance from the bending apparatus inside the eyes. A person with hyper-sighted eyes of 1.00d. has to bend his eyes 1.00d. in order to see distant objects clearly. At 40 inches, he has to bend his eyes 2.00d. At 40 inches, he has to bend his eyes 1.00d. more than a person with neutral eyes. *This bending is done automatically and unknowingly by the person.*

A person with hyper-sighted eyes of 2.00d. has to bend his eyes 2.00d. for distant seeing and 3.00d. more for reading at 13 inches. He has to bend his eyes 5.00d. which is 2.00d. more than a person with neutral eyes would have to bend. It should be readily understood that hyper-sighted eyes are not suitable for prolonged near-seeing. At far-far distances, hyper-sighted eyes, if not spoiled, can see better than neutral, normal or perfect eyes. They are better for star-gazing.

Hyper-sighted eyes of as much as 4.00d. or even 5.00d., if not spoiled by prolonged near-seeing or otherwise, can see both far and near as well or nearly as well as neutral eyes, but more often they give us visible and hidden trouble. They are visible when they affect our eyes in a visible way. *They are hidden when they undermine our eyes and our health without notice, without clue and without a trace -- no medical examination can reveal it.*

There are many variations of hyper-sighted eyes. Most of hyper-sighted eyes can see both far and near. Many, especially older persons, can see far but not near. A good many have poor vision and cannot see well, either far or near. Many hyper-sighted eyes, especially in children and young persons, act like near-sighted eyes. They see well near but not far. Hyper-sighted eyes are all deficient in curvature. *They all can be benefitted by hyper-sighted glasses which are plus spherical glasses.*

It is well to divide hyper-sighted eyes into two separate classes and give each a separate name. Class 1: Hyper-sighted eyes which have 20/20 vision or better. A suitable "Hyper-far-sighted" eyes. Class 2: Hyper-sighted eyes which have less than 20/20 vision -- a suitable term is "Hyper-eyes."

Lesson 15

NEAR-SIGHTED EYES

A near-sighted eye is one that sees objects better when they are nearer than 20 feet from the eyes. Distant objects are, more or less, blurred. In optics, it is called Myopia. It is an eye that, when relaxed and flattened, has more curvature than needed to focus on the retina. The excess curvature brings the farther light rays to a focus before they reach the retina. The light rays then spread out and reach the retina with an imperfect focus, with a blurred focus. In the eye mechanism for near and far vision, being a one-way adjustment, is unable to reduce the curvature. The eye must accept blurred vision for distance.

If the size of the eye is exactly one inch and the curvature of the eye, when fully relaxed or flattened, is 41 optical diopters, it would have 1.00d. too much. It would be a 1.00d. near-sighted eye. If the eye is larger or smaller, it would make no difference. If the eye has 1.00d. more curvature than is required for the right focus, it will be 1.00d. near-sighted, if it has 2.00d. more curvature, it will be 2.00d. near-sighted, if it has 10.00d. excess curvature, it will be 10.00d. near-sighted.

Minus lenses which have minus curvatures neutralize plus curvatures. If the eye has plus 10.00d. more curvature than is needed, a minus 1.00d. lens will take it away. It will neutralize it. The eye, then, will become a neutral eye and will have 20/20 distant vision the same as a neutral eye. If the eyes have 2.00d. too much curvature, a pair of minus 2.00d. glasses will give them 20/20 vision. If a person has 10.00d. too much curvature, which would make him very near-sighted, a pair of minus 10.00 glasses will make him see distant objects as good or almost as good as a neutral eye.

Near-sighted eyes of lower and medium grades are better suited for near-seeing than neutral, normal or perfect eyes. Neutral eyes have a bend 3.00d. at 13 inches where most of near seeing is done. A near-sighted person of 1.00d. at 13 inches, has to bend his eyes only 2.00d. which is 1.00d. less than neutral, normal or perfect eyes. A near-sighted person of 2.00d. bends his eyes only 1.00d. or 2.00d. less than neutral or perfect eyes.

It is advisable for near-sighted eyes of less than 2.00d., especially children, not to use minus glasses for prolonged reading or other sustained near work.

Lesson 14

NEUTRAL EYES (new term)

The neutral eye is one which is neither near-sighted nor hyper-sighted. It is supposed to be, and it is often called, the perfect eye and the normal eye. In optics, it is called "Emmetropia." It is an eye where the curvature of the eye balances with the focus. If the eye is exactly a one inch eye, the curvature will be exactly forty optical diopters. If the eye is smaller than one inch, the curvature will be more. If the eye grows larger, the curvature will become less than forty optical diopters.

The neutral eye, when fully relaxed or flattened, is set to focus distant objects. Rays of light emanating from objects farther than 20 feet are considered to be parallel, and parallel rays or bundles of rays of light will focus on the retina of a neutral eye without change or effort. Should the object be nearer than 20 feet, then a bending of the eyes must take place in order to see objects clearly. Distant vision for neutral eyes is 20/20 (ability to read on a chart, line 20 at 20 foot distance) or better.

At 40 inches from the eyes, neutral eyes have to bend or add 1.00d. of curvature to the eyes. At 20 inches 2.00d. -- at 13 inches, which is the reading distance, neutral eyes have to bend and add 3.00d. of curvature to the eyes. At 10 inches it is 4.00d., at 4 inches it is 10.00 d. At 2 inches, a person with neutral eyes would have to bend and add 20.00d. of curvature to his eyes. A watchmaker's loop, which he wears all day long on one eye, has a plus 20.00d. spherical lens.

A plus lens will blur the distant vision of a neutral eye, but it would reduce the bending of the eyes for near work. At 13 inches, which is the reading distance, neutral eyes wearing plus 1.00 spherical glasses would have to bend their eyes only 2.00d. instead of 3.00d. It would be a big help to a person who has to read a long time. But, for distance he would be able to see much better with the naked eyes. When age sets in and the bending of the eyes becomes difficult, the wearing of a pair of plus 1.00 glasses, for near work, becomes a necessity.

It would do much good and no harm to children or adults who have neutral, perfect and normal eyes, to wear plus spherical glasses up to plus 1.00d. whenever they do sustained and prolonged near work. It would lessen the bending of the eyes in looking near and downward. It would fully relax and stretch the eyes in trying to see far and upward. It would lessen the chances of their eyes becoming poor-sighted, near-sighted and astigmatic.

Lesson 13

THE CURVATURE IN YOUR EYES

The eye is about one inch in size. It is about one inch from the cornea to the retina. To focus one inch takes about 40.00 optical diopters of curvature. This is divided between the cornea and the eye lens. The cornea has about 30 diopters of plus curvature. The eye lens, when it is relaxed or flattened, has about ten diopters of plus curvature.

The curvature of the eye lens is proven by the following facts: When the eye lens is extracted in operations for cataract, it takes about a plus 10 diopter spherical lens, in glasses, to replace it for clear distant vision. It takes about 3.00d. more for reading at 13 inches. It takes a lens of more than 100.00d. for hyper-sighted eyes. It takes a weaker lens for near-sighted eyes. A cataract lens is, ordinarily, a plus 10.00d. spherical lens.

Should the eyes grow bigger, if the growth is natural and symmetrical, it would make no difference for the focus. A larger sphere or a larger eye has less curvature. It would focus on the retina just the same as the one inch eye. Should the eye be smaller it would also make no difference. A smaller sphere or a smaller eye has more curvature to focus nearer.

It is claimed by many authorities that the far-sighted or hyper-sighted eyes are smaller eyes and near-sighted eyes are those which grow bigger. This is a fanciful assumption. *The midgets are not all hyper-sighted and the giants are not all nearsighted. The small birds cannot see farther than the eagle -- the eagle, surely, is not near-sighted.*

The natural size and the natural growth of the eyes should have little to do with being hyper-sighted and becoming near-sighted. *It is the unnatural use and the subsequent unnatural growth which can, and does, make our eyes poor-sighted, near-sighted and astigmatic.*

Note

The optical curvature of our eyes and of lenses are relative curvatures; it is similar to relative humidity.

Lesson 12

THE FOCUS IN YOUR EYES

Like the camera, the eyes have to focus for clear vision. In the camera, the photographer adjusts the camera for different distances. The eyes, likewise, have a mechanism inside the eyes which do the work of the photographer. The mechanism is composed of a plus spherical lens which is flexible. The lens can bend and assume a higher curvature for nearer seeing. It can unbend and, more or less, stretch, for farther seeing.

The eye lens is acted upon and controlled by a muscle which is called the ciliary muscle and also by a process, which is called the ciliary process. The muscle and process contract to give the eyes nearer vision. They relax and, more or less, stretch, for farther vision. The eye lens, the muscle and the process are located inside the eyes. *It is important to emphasize that the mechanism which changes the focus for near and far seeing is located inside the eyes.*

In the optical language, the bending of the eyes for nearer seeing is called "Accommodation." This is a term which is meaningless and misleading. It is meaningless because it gives you no clue as to how or what it does. It is misleading because it assumes and makes one believe that it is effortless. On the contrary, the bending of your eyes for nearer seeing, like the bending of your body, is a work of action. Often it takes lots of effort and consumes lots of energy for nearer seeing.

Unlike the camera, the adjustments of the eyes for far and near seeing is a one-way adjustment. The natural rest position for the eyes is when the mechanism assumes the position of least curvature for the eye lenses, and the least contraction for the ciliaries. This position is a far-away focus position. *Our eyes are unable to see nearer objects clearly without bending and assuming a higher curvature.*

Lesson 11

THE EYE AND THE CAMERA

The eye is a non-perfect round sphere or ball. It is called an eyeball. It is set in a socket in the bony structure of the skull, below the forehead. In the center of the eye, at the front, there is a slight elevation on the eye which is called the cornea. In the rear of the eye, where the retina is located, there is a slight depression where vision is clearest. Vision is produced by physical, chemical and psychological processes and actions.

In its physical structure and action, the eye is similar to a camera and is controlled by similar rules. The cornea is transparent and, normally, has a plus spherical curvature. It is the rigid lens of the eye which bends rays of light entering the eye. Like the camera, the eye has a shutter to control the light. It is called the iris. It works automatically -- like the camera, it has a film, for forming images, which covers the retina.

The retina is like a flower emerging from the stem. It is composed of innumerable rods and cones emerging from the stem. The stem is composed of a bundle or bundles of nerves which are directly connected to the brain. The stem is called the optic nerve. It is the optic nerve with the rods and cones which is the main factor in seeing.

The eye can see objects only in front and in a limited space. In order to see sideways, without turning the head, the eyes themselves must turn. For turning and moving purposes the eyes are supplied with six sets of muscles. Four of them to turn the eyes inward, outward, upward, and downward. The other two muscles are for oblique and rotation purposes. *It is important to emphasize that the muscles which move the eye for direction are located outside the eye ball.*

Lesson 17

HYPER-FAR-SIGHTED EYES (new term)

Natural human eyes are not the neutral (normal) eyes, but the hyper-far-sighted eyes. They are eyes with lower curvature and longer focus than neutral eyes, but flexible and active. They are able to see very far and very near. They can see better and clearer at far distances than neutral eyes. They can see more stars in the heavens. They can also see better in the dark. They have to bend their eyes slightly to see ordinary distances. It is this bending action which makes them see better than neutral and perfect eyes.

Nearly all primitive men had hyper-far-sighted eyes. It is admitted by most eye-men that nearly all children today, up to the age of four or five years, have hyper-sighted or long focus eyes. It is in childhood or adolescence that they lose their hyper and become neutral and near-sighted. Sometimes, they also become poor-sighted and astigmatic.

Hyper-far-sighted eyes may well be divided in three grades. The normal or low grade from 0.25d. to 1.25d., the middle grade from 1.50d. up to 3.00d., the higher grade from 3.00d. up to 4.50d. Hyper-sighted eyes of 4.00d. or more seldom can see well at a distance. It is a poor vision eye. It is hyper but not far-sighted. Hyper-sighted eyes of 4.00d. or more can see much better in the dark. In the dark, they can see much better with their naked eyes than with their glasses -- in the dark, they can see better than good eyes.

Nearly all primitive men had and nearly all children now, who are 5 years or younger, have eyes that are about 1.00d. hyper. Primitive man used his eyes mainly for distance, for heavenward and star-gazing. He bent his eyes for nearer seeing at intervals and only for short and momentary durations. Our children of today are compelled to use their eyes for prolonged near-seeing. They are given no chance to relax their eyes for far-distant seeing, nor to stretch their eyes for star-gazing. It is no wonder that many change, during adolescence from being hyper-far-sighted and become poor-sighted or near-sighted and astigmatic.

[Contents](#) | [Lesson 16](#) | [Lesson 18](#)

Lesson 18

HYPER-EYES (new term)

Hyper-eyes are those hyper-sighted eyes that have poor vision for distance. They have less than 20/20 vision in eye tests. They are mainly of two kinds: the poor vision eyes and the deceptive-vision eyes. The poor vision eyes are mostly older persons who had hyper-far-sighted eyes when younger. They lost the flexibility in their eyes for nearer seeing. They became unable to see clearly at any distance nearer than the stars in the heavens.

Besides age, there are many causes that make hyper-eyes unable to have clear vision even when young. The medium grade hypers of more than 1.25d. may get spoiled because of the excessive use of their eyes for near vision. The higher grades of more than 2.00d. are not suited even for ordinary civilized seeing. They easily get spoiled -- besides, they are susceptible to many ailments in the eyes and in the body.

Before any structural, fluid or any other changes take place in the eyes, poor vision hyper-eyes can have good vision by wearing full strength plus glasses. If spoiled too much they may be able to get only better vision, but not full vision. Often, hyper-eyes are and become deceptive.

Deceptive hyper-eyes are those which imitate and act like near-sighted, or myopic, eyes. Some deceptive eyes are poor vision eyes which are unable to see well, either distance or near-by. But they seem to see a little better nearer than farther. They also seem to get a little better vision from minus glasses instead of plus. Others, especially young children, lose only their distant vision. Like near-sighted eyes they can see well near-by but not far away. Also, like near-sighted eyes, they seem to regain their full distant vision with minus glasses.

These acting near-sighted eyes are really deceptive. There are many variations and they have been given many names. Here are a few: Simple myopia, Progressive myopia, School-myopia, False myopia, Pseudo myopia, Spasm myopia, Acquired myopia, Occupational myopia, Functional myopia, Temporary myopia, Neuro myopia and Postural myopia. In many cases they imitate myopia so well that they cannot be detected by the drops (mydratic) of the oculist or by the complicated testing machinery of the optometrist. *They can be revealed only by the wearing of plus spherical glasses for a certain time.*

If civilized man is to save his natural hyper-far-sighted eyes, he must provide a pair of plus 1.00d. spherical glasses for every child, to be used whenever he has to do prolonged near vision work.

Lesson 19

ASTIGMATISM IN YOUR EYES

Astigmatism is a meaningless term suitable to scare you. It means there is a cylinder curvature in your eyes. Instead of being perfectly spherical in shape they assume, more or less, a cylindrical curvature. Instead of being plus 40.00d. in every direction they have plus 40.00d. up and down which is vertical, and plus 39.50d. sideways which is horizontal. That makes it a plus 0.50d. astigmatism.

Astigmatism is corrected by neutralizing the cylinder in the eye with an opposite cylinder lens. A minus cylinder neutralizes a plus cylinder, and a plus cylinder neutralizes a minus cylinder. The axis of the cylinder must be set in an identical position. If the eye is short on plus we give it a plus cylinder -- if it has too much plus we give it a minus cylinder. The purpose of cylinders is to make the eye spherical. **IT IS THE SPHERICAL EYE WHICH GIVES BEST VISION.**

Astigmatic eyes may well be divided into low grades and high grades -- the low grades are many -- the high grades are few. The low grades, mostly, have good vision with the naked eyes. The high grades, as a rule, have poor vision without glasses. Most low grades of astigmatism are hyper or were spherical hyper eyes. They developed their astigmatism by misusing their eyes in near-seeing. Many children who wear weak minus cylinder glasses would do better if they wore a pair of plus spherical glasses for near-seeing.

There are many expensive instruments to find the exact amount of the cylinder needed, and the exact position of the axis. Unfortunately, in many cases, they are more confusing than revealing. They are especially confusing when minus cylinders are indicated.

Quite often older persons cannot accept or wear cylinders because they seem to distort the vision.

[Contents](#) | [Lesson 18](#) | [Lesson 20](#)

Lesson 20

AGE IN YOUR EYES

Nearly all persons who have neutral or hyper-far-sighted eyes can see well, both far and near, up to a certain age. They begin to have some eye trouble between the ages of forty and fifty. First the trouble starts in near seeing. They have to push their newspaper or their telephone book farther away in order to see the finer print. Later, it blurs so they can hardly read it, and it takes great effort to read.

In neutral eyes the trouble starts between the ages of 45 to 50, sometimes even later. In hyper-far-sighted eyes it begins between the ages of 40 to 45. Near-sighted eyes of minus 3.00 or more, who wear no glasses, have no near vision trouble when they get old.

It is the loss of flexibility in the bending apparatus or ciliary mechanism of your eyes that is the cause of the trouble. You can not bend your eyes for nearer seeing as well as you could when you were younger. To see at 13 inches neutral eyes have to bend 3.00d. and at 20 inches only 2.00d. That is why you can see better holding your newspaper farther away. If you get pair of plus 1.00 glasses, you have to bend your eyes only 2.00d. Again, you can see well at 13 inches. The plus 1.00 glasses make your eyes 1.00d. near-sighted and blur the distant vision.

Between the ages of 50 and 60, you lose more bending ability. Again you have to hold your near work farther away and again it begins to blur. You get a pair of plus 2.00d. glasses and again you can see well at 13 inches. Between the ages of 60 and 70 you may lose all your bending ability and you may have to get a pair of plus 3.00d. glasses to see tiny objects nearby. The distant vision of neutral eyes seldom fails. You are old. You cannot see to read without glasses, but for distant seeing you can see well with your naked eyes.

It is different with hyper or hyper-far-sighted eyes. Signs of trouble begin in the early forties and sometimes sooner. First the blur is noticed in near work, but sooner or later, the distant vision also begins to blur. Hyper-far-sighted persons have to bend their eyes even for distant seeing. When a person gets older he loses that bending ability. The vision begins to blur and there is much effort even in distant seeing. A pair of plus 1.00 glasses for distant seeing will, in most cases, make him see well again and also relieve the strain on the eyes. For near-seeing, hyper-sighted eyes have to add more plus to their distant glasses. A pair of bi-focal glasses will make him see both, far and near.

Why Eyeglasses Are Harmful For Children And Young People

Hate those glass windows: A person who wears glasses "even though he doesn't need them," needs them. He hides behind the glasses in a variety of ways. They make him feel intellectual, or they may cover dark circles or wrinkles -- or they may provide just the measure of separation he needs from himself and the next fellow. -- Ann Landers

"The man with a new idea is a crank until his idea succeeds." -- Mark Twain

It's easy to be misled into thinking a man has good, strong facial features when all he really has is a pair of large super-dark spectacle frames. -- *The Cristian*, Aug. 6, 1967

PREFACE

I have practiced optometric eyework for over fifty years. During the first ten years of my practice, I did as I had been taught to do, prescribing glasses for all cases of children and young people who came before me.

Some forty years ago I discovered the key, or clue, to what I call my own theory and method for helping eyes. We should have had this a hundred years ago, instead of what we have had. I studied it for over a year, and used it only on my own eyes until I was sure it was right, and that the old theory of wearing glasses was wrong. I had to turn from prejudice in favor of glasses to prejudice against glasses. I became bitter against that which I had been taught, and lamented the ten years I had lost in prescribing unscientific glasses for innocent and unsuspecting children and young people. If I had only used my head, I would have discovered the cause of their refractive eye troubles sooner, and how to prevent, improve, or cure them without glasses. But I was so brainwashed with the old tradition of using glasses that I had a hard time convincing myself to turn against that old tradition. Now I find that it is even harder to convince the masses against glasses.

Over the past forty years, while I have handled thousands of cases successfully, giving improvement or cure, this is only a handful compared to the masses who wear glasses. The results in the thousands of cases I have handled have proven to me that my theory and method is right, and that the old tradition of wearing glasses is wrong. However, proving it to myself is one thing, and proving it to the world is another.

I have found that the world *wants* to believe in glasses, as a supposed panacea for the refractive eye troubles of children and young people, just as they believe in God, and that one who raises his voice against glasses is regarded with suspicion, doubt, indifference and contempt. It was as if some of the eyeglasses wearers knew more about eyes and glasses than I did. In their loyalty to the old tradition of glasses, they would fight to the last ditch to save face and not be proven wrong.

In the face of much opposition, I have persevered alone in my private practice, with success, in spite of such opposition. While there was nowhere to turn to convince the world against glasses for children and young people, I was able to convince practically every individual case that came to me. However, I will never be satisfied until I have found a way to convince the world.

This book is intended for the benefit of young children mostly, who are the victims of glasses. It is written for their elders - young people, parents, teachers, nurses, and school nurses, eyemen, schools of eyework, and all concerned who are the guardians of these children. They are the ones who will have to read it, understand what I have to say, and do something about it. Until this is done, there is no hope for the future welfare of the eyes of the present and future generations of children and young people, who will be forced to resort to glasses.

My writings are based on my own studies and experiences of fifty years, covering thousands of cases, without references, bibliographies, or the documentation of others. Unless one has watched cases as I have, over a long period of time, he cannot know what the eyes can do without glasses, and what can be done otherwise. I was never interested or impressed by articles that "quote-unquote" writings of others, with many references, bibliographies, or documentations. I have already read most of them, and I see no reason for reading them again and again in articles written by others who had little or nothing else to say. Let's leave them for students to make a thesis. I am now interested only in helping eyes, in a way that we should have followed years ago.

Be it known that I am not a follower of any other method. My theory and method is my own, and is not to be confused with any other method. However, I do give credit to another method which, before mine, declared that glasses were ruining the eyes of those who wear them. While I now agree that this is true, I am mostly concerned with the eyes of children and young people under the age of thirty-five. Older people will have to resort to glasses; it is too late for them to respond to corrective measures. But it is never too late to do something for the eyes of children and young people under my theory and method.

J. J. Kennebeck, O.D.

CHAPTER I

BASIC EYE PROBLEMS

This book will attempt to bring out and expose the causes of refractive and muscular eye troubles, pains, strains, and headaches, in cases of children and young people, and why glasses and contact lenses are not scientifically correct for them. If this can be done, then it will prove that all schools of eyework, all eyemen, including myself, and millions of eyeglass wearers have been wrong in what they have been doing and have believed in for many years. I was guilty for ten years.

Human eyes are doing so badly with glasses that they could not do worse without them. It may seem that it is just the other way, but nothing in the healing art could appear so right and be so wrong as glasses, as the supposed remedy for refractive eye troubles.

Let us forget about glasses and contact lenses long enough to consider what I have to say. We will start all over, right from the cradle. I will try to write this in plain language that the average person can understand.

I will be mentioning circular ciliary muscles, accommodation, and dynamic skiametry. For those who may not know what they are, the circular ciliary muscles are the muscles of accommodation of the human eye; accommodation is the focusing of human eyes at all distances from far to near; dynamic skiametry is the use of what is known as the retinoscope to look into the eyes at a distance of thirteen inches, the patient looking at the examiner's nose, then his forehead, then his left ear, then his chin, and back to the nose, to determine the refractive status of the transparent media of the patient's eyes. There is another version of skiametry known as static skiametry. It is done at a distance of twenty-six inches, while the patient looks at what would be twenty feet. It does not uncover that which dynamic skiametry uncovers. Therefore, I use dynamic skiametry exclusively to determine the refractive status of the transparent media of human eyes, which cannot be determined by static skiametry.

All are born with more or less weak, undeveloped circular ciliary muscles of human eyes. Optically speaking this weakness is known as plus 2.00 to plus 8.00 diopters in dynamic skiametry findings, commonly known as farsightedness. Some are born cross-eyed, caused by the same findings, in one eye or both, but mostly in both.

As the child develops, the plus dynamic skiametry findings will develop toward normal, or less plus, by the natural use of the eyes. This means that the circular ciliary muscles of the eyes will develop toward normal as they grow older, which is natural and expected, if left alone.

By the time the child is five years old, his eyes will have about half as much dynamic skiametry findings

as he had when born. By the time the child is ten years old, his eyes will have about half as much plus dynamic skiametry findings as he had at age five years, and so on as he goes through life. If left alone up to the time when his circular ciliary muscles and dynamic skiametry findings are normal, or near normal, many cross-eyes would be straightened. For the few that may not develop fast and far enough, or may over-develop, and the cross-eyes that may not straighten quickly enough, there are corrective measures. These can only be determined after an examination under the proper theory and method.

Most eyes can go through life, or at least up to age forty, without glasses, providing they were used right from the cradle. If some do not, these used their eyes wrong, and glasses are not the remedy, regardless of what type of refractive or muscular eye trouble they might have, caused by what they did wrong.

Before going into real refractive eye troubles, let us take up astigmatism and muscular imbalances, so that the finger can then be put on the cause of real refractive eye troubles.

Let us ignore and make little of astigmatism, instead of making a big case of it. Astigmatism will also tend to grow normal, if let alone, as one grows older. Making a big thing of astigmatism is making little of the real refractive eye trouble. Everyone can get along and see in their way through astigmatism over a period of time, as their circular ciliary muscles develop by the natural use of their eyes. As they grow older, if left alone, the eyes will round out, and the astigmatism will disappear.

Those who talk the most about their astigmatism, usually have only a slight case or none at all. They were horrified when they were told they had it. It sounded like they had some kind of a twist in the eyes, or a disease. They take the glasses and wear them faithfully from then on, telling everyone they meet that they have astigmatism, as if glasses improved or cured it. They don't know what it is, but they have it because the eyemen said so. Many eyemen know that when they tell a patient that he has astigmatism there will be no questions asked, and that the patient will take the glasses without argument.

Astigmatism is no more than a slight off-shape of the eyeball, due to lack of internal tone and pressure, allowing the eyeball to sag out of round in its socket. It amounts to little or nothing, and should be ignored in most cases. However, there is one type of astigmatism that might be classified as real. These cases are few and far between, compared to ordinary astigmatism. It is called structural astigmatism, of a more or less high degree, up to five diopters, rarely more. It could be due partly to sectional accommodation of the circular ciliary muscles. However, if left alone it, too, will tend toward normalcy over a period of time. If glasses are prescribed and worn, it will become permanent.

There are five kinds of astigmatism: plain farsighted, compound farsighted, mixed, plain nearsighted and compound nearsighted. The last three were formerly the first two. They changed from the first two, just the same as plus (farsightedness) changes into minus (nearsightedness); this will be explained under the heading of the cause of farsightedness and nearsightedness.

Like astigmatism, let us test for, record, and then ignore any and all muscular imbalances. They are the result of and caused by the off-normal circular ciliary muscles. As the circular ciliary muscles improve

over a period of time, by the natural use of the eyes as they grow older, the muscular imbalances will improve and tend toward normal if left alone.

The circular ciliary muscles are the opposing muscles of the four extrinsic muscles. When the circular ciliary muscles are weak and undeveloped, the nerve force they do not get goes into one of the extrinsic muscles, causing it to over-contract, which in turn causes the muscular imbalance. As the circular ciliary muscles develop, taking up more and more nerve force, the nerve force is taken away from the over-contracted extrinsic muscle which is getting too much, allowing the muscular imbalance to improve or disappear. A one-eyed person has no extrinsic muscular problem. He can have only a circular ciliary muscle problem.

So let us ignore astigmatism and muscular imbalance, and blame all refractive eye troubles on the circular ciliary muscles.

If the circular ciliary muscles and the subjective tests are normal, there is no eye problem. If there is an eye problem, it has to be the fault of the circular ciliary muscles. It is nothing else. It could not be any other part of the human eye. The circular ciliary muscles are the key to any and all refractive eye troubles. To know the circular ciliary muscles is to know the cause of eye problems. The only exception might be amblyopia, which is the fault of the retina, optic nerve, or visual centers of the brain. Amblyopia means a dullness of vision that no lens will improve. It is not the fault of the ciliary muscles; therefore it is useless to try to fit a lens to an amblyopic eye. However, my corrective measures might improve amblyopia better than any other way.

To cite one case of amblyopia, or sub-normal vision, in both eyes: (Usually amblyopia is found only in one eye.) This case was a Miss W., age eleven; visual acuity was 20/70 poor in each eye. Dynamic skiametry was plus 4.00. She read only #6 type poorly at close range. In the Subjective (chart) test, no lenses would improve visual acuity. Esophoria, which was difficult to get, was 4 degrees at 13 inches, and 8 degrees at 20 feet. This case had been examined by several other eyemen, who could do nothing for her eyes. According to my theory and method, I ignored the esophoria, and no glasses were prescribed for wear. I gave corrective measures for the dynamic skiametry findings alone; nothing else. Checkups were made every two weeks for some time, showing no improvement in visual acuity. She seemed to have little trouble in school. However, we persevered, having the full cooperation from the patient and parents. We continued the corrective measures for the dynamic skiametry findings, when suddenly her visual acuity improved to 20/40, and two weeks later, to 20/20. Her dynamic skiametry findings improved from plus 4.00, to much less plus. I did not bother to take the muscular test.

This case had another affliction, that of sloughing or peeling of the skin of both hands and both feet. She had been to dermatology clinics for this, and her case was shown at medical meetings and conventions. I did not know whether or not there was any connection between this condition and her amblyopia. It seemed that dermatologists could do nothing for her. However, her amblyopia did finally respond to my corrective measures, but it took perseverance and full cooperation.

Dynamic skiametry is the key test of the circular ciliary muscles, along with the subjective (chart) test being the key test of the visual acuity. These two tests are the keys to all eye problems. Of the two key tests, the dynamic skiametry test is the most important to know, as it can be used even on an infant, or an illiterate who cannot have a subjective test or a muscular balance test. Without the dynamic skiametry key test, one could not know the eye problem. Static skiametry will not reveal the latent circular ciliary condition. Unless one is expert in determining dynamic skiametry tests, he cannot know the deep-seated fault of the circular ciliary muscles.

Dynamic skiametry tests should be done at thirteen inches from the patient, with the patient (if old enough) first looking at the examiner's nose, then his forehead, then his left ear, then his chin, and back to his nose. In this way, the examiner can test at several angles, through the transparent media of the eyes, to ascertain the dynamic skiametry findings, neutralizing them by turning lenses in the phoropter to measure the latent error. If the child patient is not old enough, the examiner can proceed as above, as the child's eyes wander around, watching the examiner, and the examiner can estimate the plus dynamic skiametry findings.

Since children who are too young, or illiterates cannot undergo a subjective test, they should be left alone rather than fitted or misfitted with wrong glasses. Skiametry findings alone are not enough to prescribe glasses for them. It's the poorest kind of guesswork. However, children will wear whatever is prescribed for them, whether the glasses are right or wrong. They love the novelty of the glasses; they even want to sleep with them on. Because of this, it looks like the glasses are a perfect fit, that the eyeman did a good job, and all seems well. The eyes conform to the wrong lenses, becoming what the glasses make them, and that is anything but good. They would all be better off if left alone while their eyes are in the process of developing toward normalcy. Usually the lenses are more or less high plus, which retards or stops natural development. It would be worse than the plus lenses if the examiner were foolish enough to guess at and prescribe minus (nearsighted) lenses, for a patient at such a young age. We all know what we have been doing for them; I say it is wrong, and I would like to put a stop to it.

Along with the dynamic skiametry findings, and, if possible, the subjective test, we should know the symptoms - whether they say they can't see, they see double, print runs together, they have pains, strains, or headaches, etc., or they feigning eye trouble just to get a pair of glasses, or malingering, or not doing well in school. Heretofore all such symptoms ended up with a pair of glasses as a supposed panacea for eyes, which they are not.

Let us analyze the symptoms, expose the cause, and then analyze why glasses are not scientifically correct for them. Regardless of the refractive eye condition, the dynamic skiametry findings, or the subjective test, they brought on their own symptoms by misuse and abuse of their eyes in any and all close work, such as reading too much, often with head in hands, on their elbows, on the stomach, on the floor, or reading prayer books the way they do in church; by writing, drawing, sketching, coloring, comics, girls crocheting, knitting, sewing, cutting out paper dolls, boys making model airplanes, cars, boats, keeping stamps and coins, picking at their fingers, etc. All of these were done the wrong way, the hard way-too hard, too close, too long, without looking up and away. In short, they caused their symptoms themselves. If they had not done any of the things mentioned above, there would be no eye

troubles and therefore no glasses. If there are eye troubles, they did too much of what I just outlined.

Some go nearsighted just from having tried on someone else's glasses foolishly, to see if he could see with them. Depending on the strength of someone else's lenses, and how long he left them on, it could happen that quickly. No one should ever try on someone else's glasses for any reason. After even the slightest nearsightedness is once acquired, such cases should never look through binoculars, opera glasses, field glasses, or telescopes. They are worse than glasses. But it seems that these cases will do too much of the very things they should not do, and then wonder why their nearsightedness gets so bad, so quickly.

Because of what they did, they will have to pay for it by getting worse with glasses, or getting better quickly or slowly without glasses. They need discipline in the use of their eyes, in any and all close work, and corrective measures are necessary for those who might need help. Many will improve by themselves, if they will stop that which caused the eye trouble. Over a period of time they could become normal. Again I would say that they caused their own symptoms by the misuse and abuse of their eyes, in any and all close work, and that glasses are not their remedy. There are no exceptional cases where glasses might seem to be the remedy.

Cross-eyes, called esotropia, should be classified in a category of their own. They do not necessarily cause it themselves. They are afflicted with it, in most cases. Practically all cases I have had had a high diopter plus 4.00 to plus 8.00 dynamic skiametry findings, meaning weakness of the circular ciliary muscles, making for an over-contracted internal extrinsic muscle. In other words, what nerve force the circular ciliary muscles did not get got "off the track" into the internal extrinsic muscles, over-contracting them and causing the eyes to cross. Some cases-not all-have been made to look straight with high plus glasses for wear, which I say was a poor straightening. The high plus lenses not only prevented circular ciliary muscle development that would have taken place in time, if left alone, but paralyzed the action of the circular ciliary muscles. I did that myself for ten years, until I discovered it was wrong and unscientific. Just how it made some eyes look straight with glasses on I'll never know, and I don't think anyone else knows. However, during forty years of my theory and method for cross-eyes I used an entirely different procedure, without using glasses, developing the circular ciliary muscles toward normal and straightening the eyes, at the same time, in a number of cases. Some straightened at once and others took a little longer. However, all had to continue my corrective measures for some time thereafter, in order to continue the further development of the circular ciliary muscles that caused the cross-eyes in the first place. I have straightened some cases even after one, two, or three operations had failed. In an operation (tenotomy) for cross-eyes, there is a high percentage of risk and failure. In fact, they have to wear high plus glasses thereafter to try to hold the eyes straight. We can do better than that. I found out that practically all cross-eyed cases are the same, and practically all call for and respond to the same procedure, under my theory and method. Cross-eyed cases can be left alone, to watch and wait for improvement, or if eyemen think they must prescribe some kind of glasses, he could prescribe weak mild plus one lenses for wear, not high plus, as they would have ordinarily done before.

The "patch over one eye" system, used in some cross-eye cases and also in amblyopia, is a feeble effort that can do little if any good, especially in cases of cross-eyes. It stands to reason, that the minute a patch

is put on the good eye of a cross-eyed case, there is no incentive for the eyes to straighten. In fact, it retards straightening. I discarded the use of a patch forty years ago as not being a true scientific effort. Even under the old theory of cross-eyes, or amblyopia, a powerful plus lens over the good eye would do better than a patch. The patch is used for want and need of a better procedure. The same goes for prescribing of more or less strong plus lenses for wear in cases of cross-eyes. The straightening of cross-eyes, with more or less strong plus lenses for wear, if they do make the eyes look straight with glasses on, is a poor straightening, and accomplished at the expense of stopping the development of the circular ciliary muscles. Any other method would be better than that or the patch over one eye.

Following are eight outstanding cases of cross-eyes, picked at random, ones that I remember well; ages are from seven to seventeen years. All are 100 per cent improvement cases, where the eyes not only were straightened, but the high plus refraction was made normal without glasses. All wore high plus glasses for some time before coming to me, and the eyes were crossed, with and without their glasses. All were cured under my theory and method of corrective measures. As said before, while some cases straightened in the first visit, and others in a short time, all had to continue the corrective measures long enough to improve or cure the plus refraction which caused the eyes to cross in the first place.

For the record, the names were John D. (age 16); Mary D. (age 17); Georgette L. (age 17); Cynthia B. (age 7); Beachy M. (age 16); Tom J. Jr. (age 14); John G. (age 15); and Richard O. (age 7). I have many other cases to my credit. They were all the same type of case. But if I did no more than what I did for the above eight cases, it was positive proof to me that my theory and method was correct, and that glasses were wrong for them. There's a long story attached to each one of them - too long to go into here.

In my forty years of practice, under my own theory and method, I have had only one or two cases of cross-eyes that were not like all the rest. Most cases showed high plus dynamic skiametry and subjective findings, along with the cross-eyes. The results I have had without glasses and with my corrective measures-borders on accomplishing the impossible.

The first case of cross-eyes I tackled with my own theory and method of corrective measures, was John D., age 16. His eyes straightened in the first visit, after being crossed for some sixteen years. It proved to me that my theory and method was right. Subsequent cases further proved to me that it takes more than glasses can ever do for any case of cross-eyes, to accomplish what can and, should be done. (Be it understood that I had already handled other types of cases successfully.)

If I told here and now what I do in corrective measures under my theory and method for cross-eyes and other types of cases, too many eyemen would laugh in my face and ridicule me to save their face, and not be proven wrong for what they have been doing all these years. They would declare that they knew it all the time, when their records will show otherwise, and that they did not know it all the time. That is why I say that corrective measures can be determined only after an examination under the proper theory and method. I feel that I am sticking my neck out far enough by making known my feelings against glasses for children and young people, without disclosing what I do or use in corrective measures, other than glasses for wear, for them. I am exposing my hand this much. If the masses of children and young people

will take the first step and do what I have said, all will begin to improve or cure, even without corrective measures. This means that the children and young people will have to do the best they can by stopping their bad eye habits in any and all close work, by never resorting to glasses in the first place, and discarding the glasses already worn. If they will not do that much, corrective measures will be useless.

(Schools of eyework and eyemen can draw their own conclusions of what my corrective measures might be from what I have had to say, or they can contact me for the information. However, if they choose to contact me for the information they will have to admit, in their request for it and over their signature, that they agree with what I have had to say. If too few apply for the information, this offer will be withdrawn.)

It may seem that glasses can do only good and not harm, but the fact is that glasses can do only harm and not good for them, all arguments to the contrary notwithstanding. If all glasses were kept off or taken away from all children and young people who wear them, all would begin to improve. Not one would be hurt, go blind, or even half-blind, and all would be better off in the long run. There is no halfway measure. It must be all the way-glasses off. If one wears glasses part-time, he must grow worse. If one does not want to grow worse, he must give up glasses for all time.

Through a twist or blur in the vision, or any symptoms of pains, strains, or headaches which they caused themselves, they will become glasses conscious and resort to glasses. Then they will keep up their bad eye habits, in any and all close work, with the use of glasses. Soon-in a year or so-the same symptoms appear, this time with the glasses on, and they will be told they need a change of lenses. This goes on and on thereafter, as the eyes grow worse. If they had been disciplined in the use of their eyes and no glasses prescribed in the first place, this would not have happened.

Those who wear glasses for pains, strains, or headaches, soon have them again with the glasses, and they are the biggest users of headache powders. Headaches come from many things, such as exposure to fumes of fresh paint, varnish oils or gases, indigestion, gastritis, etc. Certainly glasses are not the remedy for these causes of headaches, but too many put on their first glasses because of such headaches. Whole families have put on glasses because of paint and varnish fumes while redecorating inside the home, wearing the glasses forever after. The eyeman should have traced the cause of the headaches to the fumes, and not to the supposed need of glasses. Headaches caused by fumes can last for some time, even after the fumes are cleared. But after getting unnecessary glasses and the fumes clear, the headaches are no more, and credit is given to the glasses. They continue to wear the glasses for fear of the return of the headaches.

All glasses are fitted, by all eyemen, in all cases, at twenty feet or its equivalent. Twenty feet is only one point where eyes look, from near to far, in all directions. Particularly in myopia, there is no lens that can be made to scientifically fit the eyes to all other distances. No one uses his eyes at a distance of exactly twenty feet all the time.

Glasses fitted at twenty feet are harmful and habit-forming at twenty feet and beyond. Few, if any, use

their eyes beyond twenty feet as much as they do inside of twenty feet. Inside of twenty feet the glasses are many times worse. Glasses are wrong at every foot inside of twenty feet. At ten feet the glasses are *twice wrong*; at five feet they are *four times* wrong; at one foot, they are *twenty times wrong*. This is arrived at by dividing the distance eyes look into twenty feet, to determine how many times the glasses are wrong. This is the reason why glasses are not scientifically correct, and this reason alone should turn the masses against glasses. (This does not apply to cases after cataract removal.)

There are those who would try to discredit me, to save face and not to be proven wrong for what they have been doing all these years, loudly proclaiming that eyes will compensate through glasses made for twenty feet to see at all other distances. That is true as long as they are young enough to do it. I always knew that. But I must warn you, eyes cannot compensate through glasses made for twenty feet for all other distances, **WITHOUT BEING HURT**. This is why and where glasses fall down. This is what brings on the progressiveness of myopia, which could have been prevented if the glasses had never been prescribed or worn.

There are those who know that the above is true, who will prescribe bifocals, which is a feeble effort which can do little or no good. They know that myopic lenses, fitted for twenty feet, are too strong for close work. What they do not seem to realize is that there are nineteen other feet, inside of the twenty feet, where the myopic lenses are too strong. Besides, children and young people do not like bifocals, and will not bother to look through the bifocal part for close work, looking over the bifocals most of the time. Myopic cases continue to progress, in spite of the bifocals.

There have been many articles in our eye journals expressing concern about the cause of myopia (nearsightedness) of children and young people, and what to do about it. It is something to be concerned about; it has gone too far and gotten out of control, using the old tradition of glasses as a remedy. Old-timers in the optical supply business remember, and agree, that up to twenty-five years ago their stock of already ground but uncut lenses was mostly farsighted lenses. Today, most of their stock is nearsighted lenses. Today, most of the prescriptions for glasses for children and young people, whether ready-made, or specially ground, are of the nearsighted variety. Today, making children and young people see with nearsighted glasses is considered to be not only a skill but an art, when, in fact it is placing too much confidence in glasses on the part of the one who does the examining and prescribing, and the gullibility of those concerned, the ones for whom the glasses were prescribed.

While the articles in our eye journals are more or less alike, one recent article concerns itself in great detail as to whether nearsightedness grows progressively worse faster or slower with single vision or bifocal nearsighted lenses. Nearsightedness grows progressively worse with either or both. The writers seem to think that they must allow the patients to see clearly, with nearsighted glasses, while at the same time trying to prevent progression. This cannot be done. But such articles do show that some eyemen are concerned about the progression of myopia in cases of children and young people. None of them advocate, as I do, deliberately removing glasses for everything and anything, and disciplining them in the use of their eyes in any and all close work, which was and always will be the cause of their nearsightedness.

Progression of myopia cannot be stopped as long as the patients are allowed to wear nearsighted glasses (single vision or bifocals), at any time. It can be stopped, and the myopia can be improved or cured, by not allowing that just mentioned, and by disciplining them in the use of their eyes in any and all close work. Let those concerned think about that for a while. Parents can do that much themselves, without even consulting an eyeman. The parents should watch and wait for the nearsightedness to improve or cure itself over a period of time.

There is another scientific reason why nearsighted glasses, in particular, are unscientific and wrong for children and young people. We all know, or should know, that normal eyes accommodate three diopters of power to read at thirteen inches, relaxing to a state of rest when looking up and away; not so with nearsighted eyes and glasses. Nearsighted eyes have to over-accommodate through nearsighted glasses to read at thirteen inches, as compared to normal eyes. Their over-accommodation adds up to the nearsighted lens power they wear for distance, say for example minus three diopters, plus the same three diopters that normal eyes use to see at thirteen inches, which makes six diopters of accommodation used by such nearsighted eyes through nearsighted glasses. In cases where the eyes are six diopters nearsighted, they use nine diopters to read, and so on, whereas normal eyes only use three diopters to read. Such reasoning applies to all other distances inside of twenty feet.

Just as misuse and abuse of the eyes, or over-accommodation, in any and all close work, causes the nearsightedness in the first place, such terrific over-accommodation through nearsighted glasses, causes the increased progressive nearsightedness in the second place. Part or all of such over-accommodating locks the refractive media of the eyes into more and more nearsightedness, or over-convexity of the eyeballs. Children and young people can see through nearsighted glasses, at all distances, as long as they are young enough to do it, but the nearsighted lenses will prevent improvement of the nearsightedness. In other words, nearsighted glasses and also farsighted glasses will create more of the same problem for which the lenses were prescribed and worn. If left alone, without glasses, and the bad eye habits in all close work were stopped, the eyes would return towards normal.

Under the old tradition of prescribing glasses for the eyes, the same eyeman who will harness up the accommodation with the strongest plus lenses the eye will take in hyperopic or farsighted cases, will prescribe minus lenses that will force the eyes into over-accommodation in nearsighted eyes. This does not make scientific sense. If accommodating is supposed to be bad for farsighted eyes, it is worse for nearsighted eyes. We should allow farsighted eyes to accommodate to see and overcome their own weakness, developing toward normal over a period of time, and we should prevent nearsighted eyes from over-accommodating, relaxing the circular ciliary muscles toward normalcy over a period of time, both without glasses. Therefore, prescribing plus or minus lenses in cases of children and young people is doing worse than doing nothing for them, regardless of the type of case, or whether or not there is a better method for them.

CHAPTER II

WHY WEAR GLASSES?

No one is blind without glasses. Anyone who can see with glasses can also see, in a way, without them, at least well enough to get along until his eyes improve. Only the blind ARE blind, and they cannot see even with glasses. Too many of them are blind from wearing glasses. Let it be understood that nearsighted eyes can do close work easily without glasses.

The severe cases of today were the mild cases of yesterday, just as the mild cases of today will be the severe cases of tomorrow, from wearing glasses. There are eye troubles—that is true—but no one is so bad in the beginning that he has to resort to glasses and wear them as he does, to supposedly see with or to supposedly save his eyes. One might be able to see with glasses until they need changing, but the glasses will not save his eyes. Of course if one does not live very long, it makes little or no difference if he wears glasses, but no one knows how long one will live. If one lives to a ripe old age, he will have the poorest eyes, at middle age and past, if he wore glasses before. Therefore, one must fight off glasses at a younger age to have the best eyes at an older age. One cannot wait until it is too late to do it. No one would be hurt by fighting off glasses, as much as all are hurt who resort to glasses.

Loyalty to the old tradition of glasses is widespread, and practically universal. As said before, all must save face and not be proven wrong in what all have believed in throughout the years. If all were as loyal and true to their eyes as they are to glasses, all would be better off in the long run. But all have more confidence in glasses, and less confidence in their eyes; too bad. Those who wear glasses think that they are wiser than those who do not, and will not wear them. Why be so loyal to glasses, when glasses are not loyal to eyes?

To know more about lenses is to better understand what they are. There are spheres, cylinders, and prism lenses. It has been said that a prism is not a lens. The fact is that all lenses are prisms, pure and simple. Spheres and cylinders are prisms to the circular ciliary muscles, just the same as prisms are prisms to the extrinsic muscles. The spherical lenses are cone-shaped prisms, having a curvature. The curvature is there to make them useful as lenses. Without the curvature, they would be useless. The cylindrical lenses are V-shaped split prisms, having a curvature for the same purpose as for spheres. Plus spherical and cylindrical lenses for wear kill the action of the circular ciliary muscles. Minus spherical and cylindrical lenses, for wear, over-develop the circular ciliary muscles. If left alone, without glasses, the circular ciliary muscles would tend toward normal.

With plus or minus glasses, the circular ciliary muscles will tend to grow farther and farther away from normal. Plus lenses are sedatives to the circular ciliary muscles of farsighted eyes that are in need of a stimulant, or development. Minus lenses are a stimulant to the circular ciliary muscles of nearsighted

eyes that are in need of a sedative, relaxation, or underdevelopment. In other words, the circular ciliary muscles of farsighted eyes need building up, while the circular ciliary muscles of nearsighted eyes need toning down. Either or both will do that, over a period of time, if left alone. The wearing of glasses, for either or both, does just the opposite.

Prisms are rarely fitted for wear, for muscular imbalance, for obvious reasons. The muscular imbalance could never improve, and would only worsen, with prisms for wear. Certainly no eyeman would fit powerful base out prisms for esotropia, or cross-eyes. Every effort would be made to straighten cross-eyes, in some way, without prisms for wear. Therefore, if one would not prescribe base out prisms for cross-eyes, he should not prescribe prisms for wear, or for any other muscular imbalance, tropia or phoria. Patients will have to live with whatever muscular imbalance they have without prisms for wear. In severe cases of vertical or horizontal imbalance, causing double vision, the patient will have to close one eye, when necessary, until the imbalance improves itself, or be improved by corrective measures, or both.

Since spherical and cylindrical lenses are also prisms, particularly to the circular ciliary muscles, by the same token they should not be prescribed for wear. With them, the circular ciliary muscles could never improve, and would only grow worse. It stands to reason that the circular ciliary muscles could never get better with plus or minus spherical and cylindrical glasses for wear. They have to grow worse. They would get better and not worse without spherical and cylindrical prism lenses. It can be no other way.

In orthoptics, or so-called vision training, one tries to improve the muscular imbalance, usually using prisms, base opposite that found in the eye examination, to supposedly build up the ductions. Since muscular imbalances are the result of, and caused by, off-normal ciliary muscles, this is a waste of time, and an unscientific procedure; treating a condition, and not the cause. Therefore, prisms are only useful in the eye examination to measure the muscular imbalance; they are useless otherwise. We should test for, record, and know the muscular imbalance, and then ignore it. Then if we do not prescribe plus or minus spherical and cylindrical prism lenses for wear, the circular ciliary muscles and the muscular imbalance will improve over a period of time, and especially if we stop our bad eye habits.

Previously I tried to show that the plus found in the eyes through dynamic skiametry, in infancy, will grow toward normal through the natural use of the eyes as they grow older, if left alone and without glasses. This is providing the eyes were used right, and all children and young people should be taught how to use their eyes right, and how not to use them wrong. However, some are bound to use their eyes wrong. In doing so, by using their eyes the hard way-too hard, too close, too long, without looking up and away-some over develop through the normal into myopia, or nearsightedness. Large pupils, pains, strains, and headaches are the first signs of one going to over-develop this way. As of today, this happens to over ten out of a hundred children and young people. Twenty-five years ago it was only a few per thousand. This is because the children and young people of today use their eyes harder, in much more close work, than they did twenty-five years ago. The way they are going today, if something is not done to stop it the score will be up to fifty or more in each hundred going nearsighted, in years to come. What is necessary is to discipline all children and young people in the use of their eyes as previously described, and never, never allow them to resort to glasses. Those who develop nearsightedness in spite of all

precautions, should be forced to do the best they can with their eyes, without glasses, regardless of the diopter or degree of the nearsightedness. Resorting to glasses will multiply it progressively.

Only children and young people are stricken with nearsightedness. Once they are stricken with even a quarter of one diopter, they are subject to it for some time to come thereafter. However, most cases are stricken with one to three diopters before it is discovered. All will go progressive if bad eye habits are not stopped, and glasses are resorted to, or both. There is no end to its progression; up to and past the age of forty, into ten, twenty, or even thirty diopters of nearsightedness.

Farsightedness is not bad or good, compared to nearsightedness. Nearsightedness is mean, dangerous, and treacherous. It is the worst refractive eye trouble that can happen to children and young people, the worst condition that eyemen have to deal with and for the patient to have. As said before, it is over-developed, over-contracted, circular ciliary muscles. It is an eyeball locked into nearsightedness, with a strong tendency to lock more and more, tighter and tighter, circular ciliary muscles. Adults are not as subject to it, but if an adult is foolish enough to use his eyes as children and young people do, and did not go nearsighted at a young age, possibly one in 500 or 1000 could go nearsighted at an older age. Then they would go progressive from there. But it is children and young people we should be most concerned about. If we can prevent them from going nearsighted, there will be few if any adults thereafter going nearsighted.

There are those who will try to discredit me, who will declare and insist that one is born nearsighted, that it is hereditary, and that the eyeballs are too long. Even if that were so, glasses are not the scientific remedy. But it is not so. As said before, no one can be born nearsighted, any more than one can be born with false teeth or a wooden leg. Infants might acquire nearsightedness from sucking their thumb or fingers, but they are not born with it. It is not hereditary. It would make no difference if the parents, grandparents, uncles, or aunts, were or were not nearsighted. Each and every one who is nearsighted had to acquire it himself. There are parents having normal eyes whose children might be nearsighted, and there are nearsighted parents whose children's eyes are normal or farsighted. One might inherit the traits that cause nearsightedness, but not the nearsightedness. Only farsightedness, or weak circular ciliary muscles, can be hereditary.

As for nearsighted eyes being too long, they could not be as long in the eye socket as they would have to be in a more or less high diopter of nearsightedness; neither could a farsighted eye be as short in its socket as it would have to be in a more or less high diopter of farsightedness. Nearsightedness is too much convexity, or refractive power, of the eyes, while farsightedness is too little convexity, or refractive power, of the eyes. For the sake of argument, let us suppose that one was born with one diopter of nearsightedness, and glasses are prescribed as a remedy. Since all grow worse with glasses, as explained previously, in a year or so the nearsightedness has progressed to two or three diopters. In another year or so, the nearsightedness has progressed to three or four diopters, and so on every year thereafter up to and past the age of forty, into ten, twenty, and even thirty diopters. They were supposed to have been born with only one diopter. Let anyone try to prove otherwise, or where the increased myopia came from.

There are too many cases of malingerers, of children and young people who feign eye trouble just to get glasses for secret reasons of their own. Because others wear them, they want to wear them. They fool their parents and the eyeman into getting glasses they secretly know they do not need. It is really a question as to whether they really fooled the eyeman or the eyeman fooled them in the deal. However, the eyeman should have suspected the patient. Since the patient demanded glasses, the eyeman had no trouble finding a lens for him to wear. In such cases, the lens is hardly ever plus, which would blur the vision of good eyes. So, during the eye examination, the eyeman turns in minus lens power, more or less, and the patient suddenly proclaims how much better he can see. Let it be understood that a normal or even a farsighted eye can see sharper through a more or less mild nearsighted minus lens, making black more black, and white more white, but the patient should not be allowed to wear them. However, the unnecessary minus nearsighted lenses are prescribed for wear, the patient is proud of and loves his glasses, and he wears them all the time. Soon his vision is blurred without them. Then soon, in a year or so, his vision is not clear as it was with them, and he demands a change. It goes on and on from there. The glasses never last and must be changed often. All this happens because the patient developed an eyeglass complex in the beginning, and the eyeman prescribed unnecessary nearsighted glasses.

It could be that too many eyemen are afraid of losing the patient, thinking that if he did not prescribe the unnecessary glasses some other eyeman would. It would have been wiser and better for the patient if the eyeman had fooled him by prescribing plano lenses, instead of mild minus lenses. The patient would not know the difference, being more interested in glass frames than lenses. Few, if any, eyemen would do this, being afraid that they would be caught prescribing plano lenses. But the plano lenses would not hurt the patient's eyes. Eyes are quick to take hold, and become what the minus lenses make them-nearsighted for life. If those who would wear unnecessary glasses wore plano lenses, they would be better off. It is hard to understand why one who supposedly does not need glasses would want to wear them.

There are probably as many wearing glasses they never should have had in the first place, as those who might have had real refractive eye trouble.

Because so many are wearing glasses, it makes it next to impossible to prove that glasses are not scientific. Glass-wearers will give all kinds of excuses and reasons why they put on their first glasses, and why they cannot do without them. They will never admit that they love to wear glasses.

Not all who have real refractive eye trouble wear glasses, and not all who wear glasses have real refractive eye trouble. It is hard to tell one from the other; you see so many wearing glasses. Glasses do not make the dumb smart, or the smart smarter, but too many wear them as a mark of distinction, with an air of superiority, to get sympathy, to cover up facial defects, failures in life or school, etc. It has been said-"He is such a nice person. Isn't it too bad that he has to wear glasses?" In too many cases they don't have to wear them, but they love to hear that. They are sure that glasses can do only good and no harm, when the fact is that glasses can do harm and no good. If anyone thinks he became better with glasses, the truth is he became better in spite of the glasses, and not from wearing them. For each one, who might insist that his eyes got better with glasses, there are millions who became worse with them. Glasses are looked upon as something sacred, something which no one should ever raise his voice against, at any time. Glasses are put on without a fight or opposition; it's "goodbye eyes" from that time on.

The Salk vaccine is for the prevention of polio; it was never intended for treatment, or as a remedy after the polio is once acquired. I often wonder how Dr. Salk overcame the superior complexes and jealousies of medical practitioners in establishing his claim to his discovery of the prevention of polio. I feel that it is going to be even harder for me to overcome the superior complexes and jealousies of ophthalmological and optometrical schools of eyework. Fifty thousand eyemen and countless millions believe in glasses as they all believe in God. It was easy for Dr. Salk, compared to this.

Pasteur was almost exiled from his country, half-paralyzed, a broken man, and almost died before he could prove his germ theory to a skeptical world. He had to fight the medical minds of his day, yet he was only a chemist. If it were not for his discovery, a great many of the people of today would not be among the living. Many so-called medical discoveries of today should be credited to chemistry. My theory and method should be credited to optometry.

Far be it from me to compare myself to Pasteur or Salk, but what I would like to do for the eyes of children and young people, is not secondary to the Pasteur or Salk accomplishments. I feel that my opposition is greater by far, than was that of Pasteur or Salk, or any other discovery. It seems that the whole world believes in glasses so firmly that it is skeptical of anyone who raises his voice against them. The skeptics so love what they think glasses do for their wearers that they would crucify the one who would hold otherwise.

Just as the Salk vaccine is only for the prevention of new cases of polio, my theory is first and foremost for the prevention of new cases of refractive eye troubles and complaints, by stopping bad eye habits in all cases and never, never resorting to glasses. However, unlike the Salk theory, in my theory cases of refractive eye trouble, already stricken and wearing glasses, can be helped, improved, or cured by stopping bad eye habits and discarding glasses.

As the germ theory is the key to infection and disease, the circular ciliary muscles are the key to practically all refractive and muscular eye troubles, pains, strains and headaches. This is proven even under the old tradition of glasses for the masses, by the fact that minus or plus spherical and/or cylindrical lenses are fitted for wear, in practically all cases, as a supposed remedy. They were fitted for the faults of the circular ciliary muscles. In doing so, they created more of the same faults for which the glasses were prescribed and worn. To know the germ theory is to know the cause of infection and disease. To know the circular ciliary muscles is to know the cause and condition of refractive and muscular eye troubles. It takes skill in dynamic skiametry to know the circular ciliary muscles. Too few eyemen have that skill. Most of them use static skiametry.

There are just so many different types of cases, such as nearsightedness (myopia), farsightedness (hyperopia), astigmatism (five kinds), in one eye, the other, or both the same; also cross-eyes and muscular imbalances, pains, strains, and headaches-all caused by and the result of off-normal circular ciliary muscles. There is no mystery about them. The mystery is in how it has been believed that glasses for wear are the remedy for any and all cases. All such symptoms and conditions can be traced back to

the cause, namely the misuse and abuse of the eyes. Stop the cause and there will be no such eye troubles.

Patients do not consult eyemen because they might have one or all of the above-mentioned eye conditions. They could live with and get along with such conditions, if they used their eyes right. They consult eyemen because they used their eyes wrong. The eyeman finds one of the above-mentioned conditions, and blames that as the cause of their complaints. Instead of telling them that they need glasses, the eyemen should tell them that they need DISCIPLINE in the use of their eyes. But both eyeman and patient think the case calls for and has to be remedied by glasses. The glasses never last and have to be changed often, always for stronger and stronger lenses, every year or so thereafter. If, in some cases, a change is not called for, the glasses were prescribed too strong the time before. Nothing could be worse than for an eyeman to prescribe too strong a lens for any type case, but it is particularly bad in nearsightedness (myopia). It is bad enough in farsightedness (hyperopia), or astigmatism of any type.

Practically all eyemen use the same system of eye examination. They take the visual acuity test, then the retinoscope, (it should be dynamic skiametry), then run the fogging method for the subjective test, to see what lens they can prescribe for the patient to wear. Of course there are other tests, but those are the most important.

The fogging method consists of starting with high plus to blur, gradually reducing the plus by quarters of a diopter until the patient can see letters on the test chart, down to about 20/50. Then the eyeman attempts to apply minus cylindrical lenses for more or less astigmatism. For this the eyeman must find the power and axis of the astigmatic lenses. He tries to find some astigmatism-more or less-in every case, as he was taught to do. Since I make little of astigmatism, I try not to find any, making little of the more or less that I might find, except in real cases of structural astigmatism, and I do not make big of that. I have seen many of them get along without glasses, and improve or turn into farsightedness, and then the farsightedness improve toward normal, by leaving them alone. Finding some astigmatism at some axis might take the patient's visual acuity down to the 20/20 line. If not, then the eyeman will reduce the plus spherical lenses another quarter of a diopter, or more, until the patient does 20/20. If the patient's eyes are on the plus side, the eyeman will then prescribe it for wear, the lens being the strongest plus the eyes would take still retaining 20/20, or nearest to artificial vision, which is supposed to be the proper and scientific thing to do. Then the eyes go into more and more plus every year thereafter, with the use of the glasses.

I would abolish and discontinue the fogging method for an eye examination. Instead of fogging down from high plus lenses, I would start at plano, turning in plus by quarters of a diopter, until the vision is worse. Then I would back up the plus until vision is best, to determine the refractive condition from the subjective test. In most cases, there will be a great difference between the maximum plus found in the fogging down method, and the **minimum plus found in the turning up** of the plus method. Thus, instead of prescribing the strongest plus the eye would take, I would prescribe the weakest plus, if I were going to prescribe glasses for wear. Since I am opposed to glasses for wear, I would use my findings, along with my dynamic skiametry findings, to determine the refractive status and the condition of the circular ciliary muscles, thereby enabling me to advise the patient what to do, as outlined before. So

much for cases on the plus side, from a dynamic skiametry and subjective standpoint.

In cases below plano, or below zero, or calling for minus lenses for more or less nearsightedness (myopia), again I would start at plano, turning in minus lenses by quarters of a diopter down, in the same way as in the plus fogging method, until the patient can do 20/20, being overly careful not to turn in any more minus than absolutely necessary, urging the patient to respond, knowing that the more minus I would turn in, the better the eyes could see. Too often a nearsighted patient will wait for the eyeman to turn in more and more minus before he will say that he can see as good as he wants to; this I would not allow. The patient is only allowed the minimum minus, barely retaining 20/20 vision. While plus farsighted eyes have a tendency toward (pseudo) astigmatism, nearsighted eyes have little or no tendency toward it. This is due to the fact that the weak plus farsighted circular ciliary muscles can and do allow the eyeball to sag out of round in its socket, causing the astigmatism, while the too strong minus nearsighted circular ciliary muscles keep the eyeball round, allowing little or no astigmatism.

Therefore I spend little or no time trying to find astigmatism in the nearsighted case. As said before, since I am opposed to glasses for wear I would use my subjective findings, along with any dynamic skiametry findings, to determine the refractive status and the condition of the circular ciliary muscles, thereby enabling me to advise the patient what to do, as outlined before. So much for cases on the minus side, from the dynamic skiametry findings and the subjective standpoint.

In any refractive eye trouble, there are only two kinds of circular ciliary muscle faults. They are too weak or too strong.

Measured in diopters, in cases of children and young people, they are born with plus 2 to 8 diopters in farsightedness, or acquire up to thirty diopters in nearsightedness after having been born with farsightedness. The lenses that it takes, in the eye examination, to artificially make see, or relieve, are only a measure of the refractive eye trouble, not the remedy. If no glasses are prescribed for wear, farsighted circular ciliary muscles will develop normally, if used correctly, and there will be no cases of nearsightedness. If used incorrectly, some may overdevelop through the normal into the nearsighted field. If no glasses are prescribed for the latter, and they are disciplined in the use of their eyes, they could return toward normal.

Children and young people do not have to have 20/20 vision to see, or to save their eyes. Twenty/twenty vision is nice to have, but not healthy if it takes glasses to do it. Beware of clear vision with glasses. The wearing of glasses can fool the wearer, but they cannot fool the eyes. The eyes will become just what glasses make them, and that is anything but good. The eyes want to be free to roam the field of vision without glasses. They want to tend toward a close relationship of focusing and fusing for any and all distances. Plus or minus lenses for wear break up that relationship, therefore, we must not deal in vision with glasses alone; we must deal in future eye welfare. No one can have future eye welfare with glasses.

The old tradition of eyes and glasses is buried deep in the hearts and minds of the masses. Most people are flabbergasted when they find out the truth about eyes and glasses; it is like the end of the world. They

believe in glasses as they believe in God. One might as well try to tell them that there is no God as to tell them that glasses do not save eyes; that eyes never get better with glasses; that eyes do not even stay the same with glasses; that all eyes grow worse with glasses. Glasses seem so proper and right that it is hard to believe that they could be so improper and wrong, especially in cases of children and young people. They might not know better, but it seems that adults should know better.

No child or young person can wear glasses without being hurt, and not one of them can be hurt as much without glasses as they all can be hurt with glasses. It is bad enough that adults put on the first strong glasses too soon, wear them too much and change them too often. If one thinks he has to wear glasses for reasons other than real refractive eye trouble, he should wear plano lenses, as said before.

Even colored or sun glasses cannot be worn without becoming habit-forming, and hurting the eyes. Eyes need all the sunshine and light they can take to make and to keep the pupils of the eyes smaller. The smaller the pupils, the better they see and the safer the future. It takes lots of sunshine and light to make and to keep the pupils small. Colored or sun glasses are very soothing, but very harmful to the eyes. They may be worn at the north and south pole to prevent snow blindness, and they may be worn under the most extreme conditions elsewhere, but the trouble is that they are worn when there are no extreme conditions. They are left on when they should be off. Too many wear them for poor reasons, other than a need. We should shade our eyes from the direct sun, and use the car sun-visor for driving. Wearing colored or sun glasses today calls for regular glasses tomorrow. I, for one, would never wear them. Do not fear ultraviolet or infrared sun rays, except under the most unusual and extreme conditions. Above reasoning also applies to light tinted lenses.

Practically all eyemen can predict how eyes will go after the first glasses have been put on. They know about what changes of lenses will have to be made every year or two thereafter. In some cases, where such a change is not called for, the lenses prescribed were too strong the time before. Eyemen do not realize, and patients do not know that there is an "end of the line" with glasses, in middle age or past. It is too late then to do for the eyes what should have been done at a younger age.

If it were known what glasses do to the eyes of children and young people, the first glasses would never be put on. But none are told how their eyes will go after the first glasses have been put on, and few, if any, seem to care. None are born with severe eye troubles they have later in life from wearing glasses. Few would have severe eye troubles later in life if they had not resorted to glasses at a younger age. The very nature of glasses especially for children and young people, is only to artificially and temporarily relieve or make see, with whatever lenses it takes at the time of examination-never to prevent, improve, or cure the refractive or muscular eye condition. Any eyeman, pinned down, would have to admit that. Let anyone who thinks otherwise try to prove otherwise.

It is too easy for a child or young person to get glasses. They have some complaint about their eyes and the parents get panicky and rush to an eyeman, who has no trouble at all finding some kind of glasses to prescribe for wear. Then all concerned are satisfied that the glasses have solved the problem, and that everything is all right. If it were not so tragic, it would be a big joke on all concerned; but it is all too

pitiful. The children and young people are the innocent victims, who themselves must pay the penalty for what was done for them. They asked for help, and were given harmful glasses. These children and young people caused their own eye trouble, and they needed discipline in the use of their eyes, not glasses.

The fault lies not with children and young people alone in this business of glasses for the masses. The fault also lies with their parents, school teachers, school nurses, schools of eyework (50,000 eyemen in our country alone), and certain organizations, supported by eyemen and the optical industry to the tune of millions of dollars a year. They promote the sale and wearing of glasses by urging in their pages of advertising to have the eyes examined at a very young age and often thereafter, assuming that the invariable remedy will be glasses, and changes of glasses for the masses. Parents do not think twice before getting glasses for their children. School teachers and school nurses should not urge or demand that students get glasses, unless they will also take the responsibility of what the glasses will do to the eyes, which they will not take. Schools of eyework teach only how to fit glasses; where the schools of eyework leave off is where I would begin.

The organizations mentioned above have impressive names that sound sincere, as if they were authorities on the subject, when they are no more than advertising agencies for the eyemen and the optical industry, to say nothing of being a lucrative livelihood for the personnel of these organizations. They too do not take any responsibility for what glasses do to the eyes of children and young people. Their business is to publish tricky advertising, urging the examination of eyes and promoting the sale and wearing of glasses by the masses.

If it were not for what happened to my own eyes at age of twelve and since, I would not be so sure of what I have to say against glasses, especially for the eyes of children.

CHAPTER III

PERSONAL AND PRIVATE HISTORIES

What happened to my own eyes at the age of twelve is happening to the eyes of millions of children today. That was some sixty years ago, but I remember it as if it were yesterday. I had no eye trouble before that. Living on a farm in Carroll, Iowa, the only comics we had in those days, were those in the *Chicago Sunday Examiner* newspaper. We did not have stacks of "comic" books, such as children and young people have today. With my head in my hands, on my elbows and on my stomach, I read the comics, lying on the floor. When I finished and got up, my vision was bleary-eyed and myopic. I figured out what caused it, but I did not report it to my parents. In those days, parents would not have paid any attention to it. A few did, consulting a poor eyeman of those days, and he fitted, or misfitted glasses. I remember a few who did that. They all grew worse and went into thicker and thicker lenses. But I quit what caused it, and without help of parents, eye doctor, drops, or glasses, my sight came back. Later on in my late teens, when I got into optics and studied for eyework, as students testing and examining each other's eyes, I found that my eyes were perfect.

I now know that if my parents had taken me to an eyeman, that he would have fitted, or misfitted me with nearsighted glasses, and if so, today my eyes would no doubt be of high diopter nearsightedness, possibly up to twenty-five diopters, all because I once used my eyes wrong by reading comics on the floor. I know now that it takes only a few minutes of using the eyes in the wrong manner to cause the first nearsightedness, and that keeping up such bad eye habits, with or without glasses, brings on progressive nearsightedness. Of course, it gets progressively worse faster and farther with glasses than without them.

Rather than allow even one child or young person to go nearsighted, it would be best to watch all of them carefully to prevent it in the first place, or improve it in the second place, if they have already been stricken. Discipline in the use of their eyes is what they need, not glasses. I will get back to my own case after the following.

As a typical case, a fifteen-year-old girl, a Miss A. was brought to me by her parents who knew me and my work, for an eye examination. She had never worn glasses. She was an honor student in high school, in high standing, and active in student activities. She was a bookworm. Her vision was 20/40. Dynamic skiametry was plus 2.00. Her Rx was minus .75; it was a case of pseudo-incipient myopia. I wanted to treat her case with corrective measures. She demanded glasses, stomping back and forth on the floor, saying she did not want to be a "sap;" she wanted to see like other boys and girls, with glasses. We could not reason with her. The parents weakened and had me go ahead with glasses, which I did. She was in her glory with her new glasses. I did not see her for some years. She went through high school and college, majoring in dramatics. I understood she was putting on shows in New York. Meanwhile she

went to other eyemen.

Some eight years later, at the age of twenty-three, while she was visiting her parents she phoned me for an appointment. In checking her case then, her vision was 8/200, dynamic skiametry was minus 6.00, and her Rx was minus 7.75. All such cases go more or less that way, with glasses. She wanted to know if I could help her. I asked her how long she would be here; her answer was for three or four days. I thanked her for her confidence, but advised her that her case had gone so far that I would do well, if she would do what I asked to help her in three or four years, or more.

Since she could not stay, or do what I called for, I advised that the next best thing for her to do was to use her glasses as little as possible - only for emergencies or something important, and never for close work. Even then she was stubborn, and would not consider bifocals, or a reduced Rx. This was nine years ago. I shudder to think of what her Rx for nearsightedness is now. No doubt she has gone from progressive myopia into degenerative myopia.

Her case is typical, and shows how eyes go with bad eye habits, which she had, and glasses as the supposed remedy. Beginning nearsighted cases never realize this. All believe that glasses will solve their case and see them through life.

Citing this one case of beginning nearsightedness, and then its progressiveness, is citing all cases. They will all go that way, more or less. This should be an indictment against nearsighted glasses, whether there is a better way or not. She would not have gone as bad without glasses as she did with glasses. Many would improve or cure themselves if they stopped bad eye habits, and never, never resorted to glasses. Miss A. who did not want to be a "sap," turned out to be a "sap" by turning to her first glasses. No doubt my own case would have gone the same way.

I cite a typical case that *did* do as I directed; the case of John R.

I checked his eyes every year for seven years, from the ages of six to thirteen. His mother brought him in every year. For seven years he checked out as normal. I gave the usual advice of how he should use his eyes right and warned him not to use them wrong.

At the age of fourteen he came to me for his checkup alone, refusing to come if his mother came with him. He must have known something was wrong with his eyes, and did not want his mother to be there if there was. On this checkup, his eyes were 20/200, and it took minus 2.00 nearsighted lenses to make him see 20/20; dynamic skiametry was plus 1.00. He had acquired pseudo-myopia sometime during the past year. I stormed about it, questioned him closely, and phoned his mother. His mother made light of it, having full confidence in me, saying "What of it? You can correct it, can't you?" I said that I could if he would cooperate and be a good patient. I traced the cause of his acquired myopia to his doing the one thing I warned him not to do - keeping a stamp and coin collection. His parents allowed him to work on his collection lying on his stomach on the floor with no more light than that which came from the television screen, in a darkened room. He did as I advised, gave up the collection, and stopped all

unnecessary close work. What close work he had to do I had him do at a distance, under lots of good incandescent light, looking up and away often, blinking and squeezing his eyes often, and I prescribed my corrective measures. However, I feel that he would have responded as he did even without my corrective measures, if he did as otherwise directed. In my case, my eyes did just that when I was his age.

In the two weeks time I set for his checkup, he was back to normal eyes, with 20/20 vision, and the dynamic skiametry findings were still plus 1.00, which I call normal. After regular checkups thereafter, in two weeks, and then once a month, he stayed normal. He is now twenty-one years old, and still normal. In fact, he passed the eye test for his military service.

His case is one of many that I could cite. If I had given him the minus 2.00 nearsighted lenses for wear, there is no doubt in my mind that his eyes would be minus 4.00, minus 6.00, or even higher diopter nearsighted today. He was saved from a life of misery with nearsighted glasses and progressive myopia. The same can be done for millions of other cases, if caught in time and before the first glasses have been put on.

Going back to my own case, after completing my studies in eyework, and becoming registered to practice in the State of Nebraska, I located in Kansas City, Missouri. At that time, Missouri had no State law governing the practice of optometry. Later I assisted in getting such a law, and became registered under it. I was associated as assistant to a well-known high-class optometrist, Dr. W., for five years. He had a high-class following and delivered eye service on a silver platter. I mention this to make a point.

Dr. W. knew the tricks of practicing eye work. The point I wish to bring out is about astigmatism, and how he used it. The same trick is still being used today by too many eyemen. Dr. W. would examine eyes and say as little as possible, knowing that sooner or later the patient would ask, "Well, Doctor, what did you find?"

Invariably Dr. W. would lean close to the patient, and in almost a whisper, he would say, "You have astigmatism," whether the patient had it or not. That did it. No more questions asked. It clinched the sale and wearing of glasses without further argument.

No doubt the patients were horrified, thinking that astigmatism was some kind of a disease or twist of the eyeballs, and that glasses would remedy it. Most of them had no astigmatism at all. In those days fifty years ago, fewer turned to glasses, and of those who did most of the cases were of the farsighted variety. There were very few nearsighted cases then. Nowadays most cases are nearsighted and fewer farsighted, with or without more or less astigmatism.

After five years of internship with Dr. W. I started out on my own. As I said, my own eyes were perfect, but because I was in the business, and to make an impression, I thought I myself should wear glasses. Since some kind of lenses can be fitted for any kind of eyes. I fitted myself with mild farsighted lenses plus .50, plus .50, axis 90. I could see as well or better without them, but as I had been taught, I thought the plus lenses would help my eyes. I also grew a mustache (it was reddish) and I wore a phony diamond

ring. I was subject to headaches before I put on my first glasses, and also after as well.

I changed my lenses often, to supposedly keep them up-to-date, up to plus 1.50, plus .50, axis 90. During all this time I thought, as I had been taught, that my eyes were getting better, because I could accept more plus lens power, when in fact I was growing worse. This went on over a period of ten years, up to the age of thirty-five.

Up to that time I was loyal and faithful to glasses as a supposed panacea for eyes, as I had been taught, and as all eyemen were taught. However, I was always concerned and puzzled about nearsightedness, and the way the eyes grew worse every year or two. In those days I tried to give orthoptic vision treatment, in an effort to prevent incipient and pseudo-nearsightedness and glasses. Even then, while not knowing the cause of nearsightedness or why it became worse with glasses, I was able to prevent and improve some cases, giving credit to the prism orthoptics, when I should have given the credit to something else.

After taking my treatments, patients would say that they thought their eyes were so much better that they did not feel the need of glasses. This I could not understand then, as I was not trying to remove glasses. I thought I was only trying to improve the muscular imbalance, along with the wearing of glasses. However, all became clear to me later, after discovering the key or clue, and working out by research what I call my own theory and method for eyes, which we should have had many years ago, instead of what we have had.

Later in life, when I was thirty-five years old, and wearing plus 1.50, plus .50, axis 90, my dynamic skiametry findings had. to be over plus 2.00, and I had headaches. When I found out the truth and the key to the cause of my eye troubles, and why glasses are wrong, I dropped glasses like I would a hot poker. By doing just that alone, I could notice and feel my eyes improving at once. Instead of wearing farsighted astigmatic glasses, I let my own eyes become active, allowing my own accommodation to overcome my acquired weakness, and had no trouble getting along without glasses.

Then to step up my improvement, I used corrective measures on my own eyes. I figured out what my corrective measures should be, how they would work, how they would feel in my own eyes, and what they would do. It worked exactly as I figured. In fact, I experimented in my own case, and used ten times more powerful corrective measures than necessary, to prove to myself that it was safe and scientific. As a result, I built up a powerful pair of eyes, with super vision both far and near. Suddenly one day my headaches were gone, and I had the grandest feeling in my eyes and head as never before, and it has lasted ever since - some forty years with no glasses, at my present age of seventy-five years.

It so happened that I caught my own eyes in the nick of time. Another one or two years might have been too late for me to prove my own theory and method to myself, in my case.

This can be done for all such cases as mine - farsightedness - if caught in time. I know where my own eyes would be today if I had not done what I did in time. I would be wearing plus 2.00 or plus 3.00

diopters or more, for distance, with a plus 2.50 bifocal for near sight, all the time. In other words, I would have a dead eye, as far as eye-focusing or accommodating is concerned, like so many of our older people of today. However, I cannot do for the older people of today what I did for myself. It is too late for them; their eyes are set in their weakness. I have to resort to prescribing glasses for them, done in my own way. As for myself, I would not take a million for my own eyes, if I had to go back to where I was before and would be today, but it is not too late to improve or cure the eye troubles of children and young people.

While I have enjoyed perfect vision in each eye, and comfort without glasses for the past forty years, at my age of seventy-five I have to watch my eyes to keep from going nearsighted. I do a lot of reading, and there are times, when I look up and away, that my distant vision is blurred, meaning that I have been reading too hard, too close, and too long, without looking up and away often enough. When this happens I stop reading until my distant vision clears up. I help it clear up by blinking and squeezing my eyes. I said before that only children and young people go nearsighted from bad eye habits in all close work done in the wrong way, but it could happen to one in many adults who use their eyes wrong, as children and young people do. I do it often, experimenting on my own eyes to see how long I have to read to do it. Then I stop reading long enough to see how long it takes to return to normal. If I resorted to nearsighted glasses for the temporary nearsightedness I brought on myself, the nearsightedness would become locked and permanent, and get progressive from there.

Such happenings to my own eyes could happen to some other adults. Since they do not understand what happened, as I do, they resort to nearsighted glasses, get worse from there, and wonder why. No adult should resort to nearsighted glasses. It is bad enough for children and young people to do it. By nature, adults should stay normal, or go farsighted for distance, with possibly presbyopia (age sight past the age of forty) for near. It is more unnatural for an adult to go nearsighted than it is for children and young people. Age and time will help an adult's eyes to return toward normal, if the bad eye habits were stopped long enough to do it. To keep it from happening again, adults should hold their close work farther away, under good direct incandescent light, and look up and away often. If adults would do as I do, they could control their eyes as I control mine.

Following is how I discovered the key clue to my theory and method, forty years ago. This was a case of pseudomyopia; a Miss Y, age twenty, occupation secretary, visual acuity 20/30. RX minus .50* dynamic skiametry plus 2.00, symptoms: headaches. Esophoria 6° at 13" and 12° at 20 ft. With orthoptics, using prism base in, I was trying to tone down the extrinsic muscles to improve the esophoria, and thereby eliminate the pseudo-myopia, or need for glasses.

* Minus .50 is a very mild nearsighted lens.

I had given only a few orthoptic treatments when one day my phone rang. The caller was a Dr. X, an ophthalmologist, saying that my patient, Miss Y, was in his office with her girl friend, to whom he was delivering glasses he had fitted for her. Dr. X said my patient allowed him to go over her eyes, and he reported that he found Miss Y should have minus .50 glasses, the same RX I found but I would not fit at the time, which I told Dr. X. He asked me why I would not prescribe it. I told him that Miss Y's dynamic

skiametry findings were plus 2.00, and that I was giving her orthoptic treatment, etc., and that if the minus .50 was prescribed for Miss Y, he would have to do it. He said something that gave me the key or clue I am telling about. He said that with *wearing the minus .50 for a week or two, the dynamic skiametry plus 2.00 findings would be gone*. There is something for eyemen to think about. It could lead to a radical and revolutionary change in ophthalmological and optometrical eye work.

While Dr. X did not realize what he said, which was true, it struck me then and there as the key to what turned out to be my own theory and method for eyes. Without saying any more than I had to, I got off the phone as quickly as I could and my head started to swim. I thought, "What did he say? Why did he not realize what he meant?" etc. etc. Little did he realize what he had said.

To this day he does not know that he gave me the key to my own theory and method. I would urge others to read that again, slowly, and see if it does not give them the key it gave me. But it was the Dr. X phone call which made this book possible.

In the case of Miss Y, I reasoned that she came to me because of her symptoms of pain, strain, and headaches, not because she couldn't see perfectly at a distance. What she needed, instead of glasses, was discipline in the use of her eyes in all close work. She had just started working as a secretary, and being too conscientious about her job, she did her work the hard way - too hard, too close, too long, without looking up and away, which was the cause of her headache symptoms. Easing up on the close work which would have improved or cured her symptoms of headaches, and therefore there was no need for the minus .50 glasses.

I cannot go into detail concerning the thoughts that came to me from what Dr. X said; I will only mention a few. What he said was that the minus .50 for wear would eliminate or cure the plus 2.00 dynamic skiametry findings. I reasoned that is what the minus .50 would do, but how? What became of the plus 2.00 dynamic skiametry findings? Something had to take place, and change. I reasoned that this was eliminating the plus 2.00 skiametry findings, and creating a worse condition. To think that the wearing of minus .50 would do that, and it would, meaning the refractive media of the eyes would have to become permanently 2 diopters more convex, and that the circular ciliary muscles would have to become stronger than they were before - too strong.

But where would more convexity take place? It would have to be in the crystalline lens, or possible the cornea. I could not believe that it could be the crystalline lens becoming permanently 2 diopters more convex; it had to be the cornea.

Then I began to doubt that the crystalline lens was the media of accommodation of the eyes, and thought that the cornea had to be that media. However, whatever media one cares to believe to be the media of accommodation makes little difference. The fact is that some refractive media of the eyes had to become 2 diopters more convex, in the case of Miss Y, to eliminate the plus 2.00 dynamic skiametry findings. The same is true of all other cases of incipient or pseudo - nearsightedness, before the first glasses have been put on. All such cases were once plus dynamic skiametry findings before they changed to

nearsightedness.

As said before, nearsighted glasses eliminate the dynamic skiametry findings while creating a worse condition, that of nearsightedness and progressive nearsightedness. I reasoned that there must be a way to improve the eyes without creating a worse condition. *There is a way.* I explained it previously; to discipline the patient in the use of his eyes and never resort to glasses. There are corrective measures to be given in cases that need more than discipline. But discipline and no glasses *alone* will help improve most cases.

Students should get the cooperation of the teachers and the school nurse, sit in or near the front row at school, and in severe cases get permission to walk up to the blackboard, if necessary, to see. Allow no teacher or school nurse to demand that the student get glasses for any reason.

Teachers should spend at least a few minutes every day in all classes up to university level, teaching students how to use their eyes right, to do all close work correctly, and to look up and away often, plus how not to use the eyes wrong, and see that students do it.

Teachers should write large, and plainly on the blackboard, keep it clean for good contrast, and see that there is no glare on it. Glare does not hurt eyes, but students cannot see through it. The students then tell their parents they could not see the blackboard that day, but the students did not say there was a glare on it, or that the board was not black, or that the teacher did not write plainly or large enough.

School nurses should do no more than screen the vision of students, and without comment or advice. As said before, no one should urge another to get glasses unless that one will take the responsibility of what the glasses do to the eyes. On the contrary, eyes are doing so badly with glasses that those who wear them should warn others not to wear them.

There are those who will say that students have to learn and get their education. That is true. But they can do that and save their eyes at the same time by doing it right. An honor student is one at the head of his class, with normal eyes. One at the head of his class with glasses is not an honor student. He hurt his own eyes trying to excel over others. It would be better to be the poorest student with the best eyes, than to be the best student with the poorest eyes. But no student has to hurt his eyes to get his education. All should do all close work right all the time. Some students can go nearsighted just by doing a minimum of close work in the wrong way.

Nature never intended that children and young people should wear glasses. It is bad enough that adults of the past and present generation had to resort to glasses. It is too late for them to do what they should have done at a younger age, in order to have better eyes at an older age. However, the future generations of adults could have better eyes than those of yesterday and today, if they use their eyes right and do not resort to glasses, at a young age.

But children and young people are told that if they wear glasses at a younger age, they will have better

eyes at an older age. That just does not make sense. Glasses can fool the young patient, and their parents, teachers, and school nurse, but glasses cannot fool the eyes. Their eyes will be just what glasses make them, and that is anything but good. Their eyes will conform to practically any lens, or glasses, that are put before them for wear. If eyes can conform to something, they can also conform toward normal. This is what nature really intended for them.

As an example or two of how glasses are looked upon, not only by adults but even by children, the one in this instance is a four-year-old little girl who spends much time at our home. She is as cute as they get, and smarter than others of her age. One evening at dinner she was listening to what I was telling my wife about a lady patient in her forties, well-dressed, attractive, who was led into my office by her husband for an eye examination that day. The lady patient had a brand new pair of glasses, fitted by a reputable clinician, with which she could not see. Without going into the findings of her case, other than to say that her eyes looked clear and normal but she could not see, nor could I make her see with lenses, and that her sight had been failing for the last year or so, I had my suspicions as to the cause. The point I wish to bring out is that when telling my wife that the patient was practically blind and that I could do nothing for her, the little four-year-old girl suddenly blurted out, "Well, if she couldn't see, why didn't you give her glasses?" - *As if glasses would make the blind see!* But the little girl really thought that a pair of glasses would solve the problem. Where she got the idea that glasses would do that I'll never know.

Another case is that of a seven-year-old girl from Alliance, Nebraska. Her parents were with her and her father, a dentist, wore glasses. The girl had worn glasses for several years. In my examination I found that she had perfect eyes, and did not need glasses or corrective measures. She was a malingerer, wearing glasses for poor reasons other than real refractive eye trouble. She loved her glasses. I ridiculed the wearing of glasses so much that the father reached up and removed his own glasses, putting them in his pocket case. But the little girl was not so impressed, or was not hearing what I had to say. Suddenly, to try to justify her wearing of glasses, she blurted out, "What about my astigmatism?" - as if glasses were a perfect remedy for astigmatism, which she did not have.

It's pretty tough when one has to fight children as well as adults in trying to prove a better theory and method for eyes, or just proving glasses to be wrong for children and young people, whether there is a better way or not. The above two cases are typical of most children and young people, as well as some adults who want to believe in glasses, right or wrong.

One might wonder - if glasses were not intended for wear, what were optical lenses intended for? Primarily, optical lenses were intended to be used in the examination of eyes, to determine and to measure the refractive and muscular eye condition. Knowing that, with the proper theory and method corrective measures could then be directed and advised. Prescribing the lenses found by the objective or subjective test in the eye examination for wear is doing less than nothing. It would be better to leave the patient alone. If there are some things they cannot do, they cannot do them until their eyes improve enough to do them.

Prescribing of plus glasses stops the development of weak or farsighted eyes, and minus glasses

overdevelop the already overdeveloped nearsighted eyes. If left alone, weak or farsighted eyes will develop toward normalcy by natural use. Some of them will even overdevelop into nearsightedness. This overdeveloping could be prevented by watching, directing, advising, and warning. Nearsighted eyes, too strong, will relax, or undevelop toward normal over a period of time without glasses, if left alone. There may not be quick cures in bad cases, but there would be improvement in all cases.

CHAPTER IV

GLASSES FOR THE MASSES

My own theory and method has to be reasonable, judging from patient reaction and by the reaction of a few eyemen who tried to imitate what they thought I was doing for eyes. Some patients passed on the words of advice they received from me to some of their family, friends, and acquaintances, who, without even consulting me, took off their own glasses, quit wearing them, and got along well without glasses thereafter. I got this information by the "grapevine."

I was happy for those who did that, even though I did not receive direct credit or remuneration. Some eyemen, when asked what they thought of me and my work, answered that they could do the same as I do for them, if that is what they wanted. This also came to me from the "grapevine." But as far as I was able to trace it, none of them did it, and none of them could do it without the theory behind my method, which they did not have.

Imitation is the sincerest form of flattery. I wouldn't be a bit surprised, if after reading what I have to say here that schools of eyework, and eyemen in practice, will change from what they have been doing to what I have been doing. Some will be honest enough to give me credit, while a few others will run with it, call it their own, and use it in their teaching or practice, as if they knew it all the time. They will do this to save face, and not be proven wrong for what they have been doing all these years. However, not one could prove that they did what I have been doing before reading what I have to say. Their records would prove otherwise, but I doubt if they would produce their records. Their records would show that they fitted glasses to practically every child and young person who consulted them.

Some eyemen claimed they could remove glasses, in time of war. They did not claim it before or after the war. It did, not take a war for me to declare that glasses can and should be kept away from new cases of children and young people, and removed from those already wearing them.

This book will not be complete without criticizing drops in the eyes, or dilation of the pupils, for an eye examination. This is done only by some, not all, ophthalmologists, and never by optometrists. There is not one good reason why it should be done. They say they do it to relax the accommodation of the eyes. If it did that, nearsighted eyes could be improved or cured, which they are not, and by the same token farsighted eyes would become more farsighted, which they do. It paralyzes the human eyeballs, and they cannot stand to be paralyzed by drops. It leaves the ciliary muscles of the eyes sluggish for sometime thereafter.

Then they would say they did it to examine the interior of the eyes. Any one skilled in eyework can examine the interior of most eyes without dilating the pupils. Only a few, compared to the many, where

an internal eye condition might be suspected, are in need of an internal eye examination.

Since dilation of the pupils does no good, it can do harm. It could be the cause of glaucoma. I have said for forty years that one who dilates pupils for an eye examination shows a lack of skill in examining eyes without dilation. Since then, I have found that many national and international authorities on eyes say the same. No one has to take my word alone against dilation of the pupils for an eye examination. In fact, a better examination of the eyes can be made without dilation of the pupils than with dilation.

Too many eyemen dilate pupils to impress the patient with the fact that he is making a more thorough examination than others who do not dilate. There have been cases of children and young people who turned blue and acted like wild animals after dilation of the pupils. I, for one, would not allow any eyeman to use powder drugs or drops in my eyes for an eye examination for any reason at all.

Without a doubt, there are going to be more severe cases of eye trouble and blindness in the future, from what is being done to the eyes of the present generation, than the world has ever had before. Conditions that cause this are detachment of the retina, myopic or nearsighted cataracts, conical corneas and glaucoma; these come mostly to eyes with glasses, especially of the nearsighted variety. Farsightedness is bad enough, but nearsightedness leads to progression, deterioration, and degeneration of the eyeballs, in the middle age or past, if glasses are worn throughout life.

Once I attended a meeting of our local association of optometrists. Sitting by myself in the back row, because other optometrists ignored me on account of my opposition to glasses, I noticed a certain optometrist sitting in the front row, wearing thick lenses of about minus twenty diopters. I thought to myself, "How long will it be - if he lives - before he will lose his sight?" He was middle-aged then.

Not too long thereafter a mother brought her young son, about age twelve, to me for an eye examination. They were of the same name as the optometrist mentioned above. I asked them if they were related to that optometrist, and if so, why had they come to me? The mother answered that he was their uncle, and that he was blind. When eyemen themselves go blind in middle-age from wearing such glasses, what chance has a patient?

I know of other cases of eyemen themselves going blind at middle-age, or past. One in particular was an internationally known eye specialist, connected with a well-known international eye clinic. A columnist once wrote about him, "The great eye doctor who exacted an enormous fee for the removal of cataracts from the eyes of the King of Siam is now himself going blind." Not too long after that, the columnist wrote, "The famous eye doctor has gone blind." Not long after that, the great eye doctor died.

About another ophthalmologist I knew personally. He had an international reputation. He wore nearsighted glasses into his older age. I think I am the only one, outside of his family, who knew that something happened to his eyes.

I used to see him coming to church, leaving his chauffeur-driven car, entering the church and back to his

car, alone.

Later he had to be escorted from his car to the back seat of the church, and then back to his car after services. I could tell by the way he had to be helped that he was blind. He was in good health otherwise. I could also tell by the way he acknowledged greetings from people that he could not see them.

Not long after that, he was confined to a hospital, until he died. I heard by the grapevine that he was blind. Neither he or his family let it be known that the great ophthalmologist lost his sight. The last time I saw him he was still wearing the nearsighted glasses he could not see with. Faithful to wearing glasses to the end. Little did he think that the wearing of nearsighted glasses after the age of forty could lead to blindness.

Regardless of what else might have helped cause the blindness, his nearsighted glasses could not have helped matters in his case, at his age.

If anyone is going to go blind, he will go blind quicker with glasses than without glasses. Glasses do not prevent blindness. Again I say let anyone who thinks otherwise prove otherwise. For each one who might have gone blind without glasses ever being worn, there are many who went blind from wearing glasses throughout life. Glasses hold out false hopes for the afflicted.

I realize I am trying to do what seems to be the impossible - trying to turn the masses against glasses. News pictures and TV show glasses being worn by people all over the world, even in the farthest outposts. It makes it look like the masses of glass wearers are right, and that I am wrong. It was not always this way; it has become this way only in the last few years.

In the business and social world too many resort to glasses, not so much for eye trouble, but to be a big shot or to imitate the big shot; to make an impression, to dignify their person, to cover up faults and facial defects, to get sympathy, and particularly for men and boys - the unwritten law, "Thou shalt not strike one who wears glasses."

Why women let themselves get into glasses I'll never know. Dorothy Parker said fifty years ago that "Men seldom make passes at girls who wear glasses." I would add my own - "Where glasses begin, glamor ends." And for all I would say, "Where glasses begin, good eyes end."

It is hard enough to expose the wearing of glasses by the few who let themselves get into real refractive eye trouble, pains, strains, and headaches, from having misused and abused their eyes in the first place. It is even harder to expose the many who really do not need glasses and should not wear them, for the reasons just mentioned. They all will fight to the last ditch to justify their wearing of glasses. Those who need glasses the least will swear they need them the most. It is next to impossible to expose the masses for wearing glasses that many secretly know they do not need.

Here is an example of how and when glasses took over almost a whole continent. A native of Africa

wrote an article for an eye journal. Glasses were hardly ever seen or heard of before this. (The native was a student of higher learning, in Africa.)

One year a white foreign teacher appeared, wearing the large black plastic framed glasses. All students were very impressed saying and thinking that the teacher must be brilliant to have studied so hard, using his eyes so much that he had to wear glasses. That year the native student journeyed to New York to study. There he saw so many wearing glasses that he put them on himself.

After several years the student returned to his native Africa, to find that most students, and many others - men, women and children - had turned to glasses, as if overnight a whole continent had become eyeglass conscious. It was the desire to wear glasses, not the need.

One might say, "So what? Let those who want to wear glasses wear them, if it gives them a lift of some kind or satisfies their ego." Well, there are two ways to look at it - two sides to the story. Do they want to save their eyes, have the best eyes, or do they just want to wear glasses? If they want the first, they cannot wear glasses. If they want the second they cannot have the first. One has to make a choice before it is too late. No one can have both. But none are advised or warned as to what glasses will do to their eyes. On the contrary, they are told that glasses will save their eyes, and they believe it without question. However, they are more concerned about the frames of the glasses on their face and what they think the frames do for them, than they are about the lenses that are fitted, or misfitted, for wear.

Millions already wear glasses, and millions will put on their first ones every year, making multi - millions wearing glasses, and then all of them have to have the lenses changed every one or two years, as their eyes grow worse. That is good business for the eyemen and the optical industry, but not good for human eyes.

There is a difference between the old tradition of eyework and glasses, and what I do and would like to have done for eyes in all new cases. Under the old tradition a new case is examined, and invariably the advice is, "You need glasses," as if glasses are the answer and will solve any and all eye problems. In all old cases, where glasses have already been worn, the advice is, "You need a change of glasses." That goes on and on ever year or two, through life. During all this time the farsighted variety of eye trouble grows progressively weaker and weaker. The circular ciliary muscles become less and less active - a dead eye, like a dead tooth - when they should be as active as the hair spring of a watch or clock, to focus the eyes from far to near and near to far, like they could have been if the first glasses had never been put on.

The nearsighted variety of eyes grow over-developed, stronger and stronger, too strong (only farsighted eyes are weak) and progressively worse with glasses. The circular ciliary muscles become more and more over-contracted, causing too much convexity of the refractive media of the eyes, like a watch or clock which is wound too tight and will not run. (A farsighted eye is like a watch or clock which is run down and needs winding.) The circular ciliary muscles are stuck in their over-contraction in nearsighted eyes.

It stands to reason that it is easier to develop a farsighted eye to overcome its own weakness - like winding a watch or clock - than it is to undevelop or relax a nearsighted eye - like trying to unwind a watch or clock that was stuck. But glasses do not develop weak farsighted eyes, and they do not undevelop nearsighted eyes. They do just the opposite, and that is why I say that glasses should not be worn.

Under my theory and method for eyes, new cases are examined objectively and subjectively. Regardless of the findings, they are told that they caused their own eye troubles and cannot have glasses. They are given a lecture of one to two hours, disciplining them in the use of their eyes. In other cases, where glasses have already been worn, my advice is, "You must give up glasses." I have not used the terms, "You need glasses" or "You need a change of lenses" in cases of children and young people for over forty years. All cases that followed my advice of discipline in the use of their eyes in any and all close work were improved or cured. The few who did not choose to follow my advice and demanded glasses, or got them elsewhere, all grew progressively worse. Some of them returned to me later, anxious and willing to follow my advice. It would have been better if they had done it in the first place.

I realize that some nearsighted cases of teenagers on up, already deep into glasses, will not do what I call for, which is giving up their glasses all the time, and that I cannot give them enough quick improvement to do their job. But they can give up their glasses at least part-time, when they are not working, or driving, etc. This alone would make their glasses last longer, without changing for stronger lenses. But too few of them will even do that much for themselves. They leave their glasses on when they could be off. It is too bad for them. They will have to pay the penalty for wearing their glasses all of the time, no matter what job or work they might do. However, some such severe cases did do as I suggested and were helped.

Those who choose to wear glasses should know and remember that others have to look at them with their glasses on. Others would sooner see their eyes, not the reflections of the glasses that are worn. There is hardly one eyeglass-wearer who is not secretly proud of his glasses. They insist on being accepted and respected with their glasses on. They would have it - "Love me, love my glasses" - no matter for what reason they wear them. Eyeglass-wearers feel that they are superior to those who do not and will not wear them. They are convinced that they can do anything with their glasses on that anyone else can do, and do it better. They cannot understand why they are not accepted for certain skills or occupations because of their wearing glasses. On the other hand, there are some skills and occupations where it is demanded that glasses be worn. Glasses do not necessarily make for efficiency, yet it is believed that they do - too much so. The time comes when efficiency is lost with glasses.

There is another reason, especially with young people, and particularly young men, why they should not have worn glasses at an early age. It is when they are of military age, or want to be a commercial flyer. Many an otherwise fine specimen of young manhood has to go into the lower ranks of the military because he could not pass the eye test for the higher branches as an officer. An army is only as good as the eyes of its servicemen. So many young men have gotten into the habit of wearing glasses at an early age that the military has to take them; they have no choice.

In World War I there were few rejects for poor eyes, and few men wore glasses. In World War II there were many rejects for military service and many wore glasses on account of their bad eyes. Today there are even more rejects for the same reason, all because they used their eyes wrong and turned to glasses at an early age. A large percentage of service men today wear glasses, and most of them are nearsighted. It is assumed that they have to wear glasses, to protect themselves and their buddies. But what about losing, breaking, bending, or smearing their glasses in the heat of battle, endangering themselves and their buddies, possibly losing the fight or skirmish, or more? It would be much better if we would start today by preventing, or curing the refractive eye troubles of our children, so that we might have the best eyes for our future military servicemen, instead of having so many poor eyes and rejects. Many young men who crave to be commercial flyers will be thwarted because they used their eyes wrong at a young age, and turned to glasses. The same applies to some other occupations, for the same reason.

The writer takes credit for getting young men into West Point and Annapolis with corrective measures after their failure in passing their eye test, and also for making it possible for many young men to make commissions in the high branches of the Army, Navy, and Air Corps in World War II. He also has helped commercial flyers, then and since, all without glasses.

Oh, the gestures that are made with glasses! Oh, how eyeglass wearers project their wearing of glasses! They would not want to be caught dead without them. I thought I had seen everything until I saw glasses on the dead, lying in their caskets. How many times have we seen would-be important men put their glasses on and off, holding them up in their hands to show that they have them, to make a point or an impression? It seems that all professional, political, scientific, and religious people think that they must wear glasses to look the part, and a lot of ordinary people wear glasses, to look smart. They all know this, but they think the world does not know it.

We also have some actors (few, if any, actresses wear glasses), who wear glasses on the stage, in pictures, and on T.V. I have seen members of panel programs put their glasses on over their blindfolds. Glasses detract from the actor, but they expect that to be overlooked. Comedians joke and make fun of others who wear false teeth, the baldheaded, and those with other physical defects, but he is sure that he himself will be accepted with glasses. I say that there are no eyes so bad and no show so long, that it cannot be done without glasses; there are plenty who can do it. The "Harold Lloyd" type of comedy with glasses is bad enough. Glasses also detract from jazz musicians. It seems that we do not want to see glasses on our actors or in the entertainment field. The fact that some wear them while acting, and that a large percentage of the professional, political, scientific, and religious people wear them, makes it hard to prove that glasses are unscientific and wrong.

Some actors and athletes turn to contact lenses to perform. While they might get by without glasses on their face, they cannot get away from the harm done by contact lenses. Contact lenses are as bad or worse than glasses. Wild claims are made for contact lenses. Eyemen who would never before admit to the faults of glasses do admit these faults after they get into contact lens work, mostly because of the greater remuneration. They claim that contact lenses will stop the progression of myopia. Just how they do that they do not say. As with myopic glasses, if nearsightedness does not call for stronger contact lenses

within a year or so, the contact lenses were too strong the time before. They could cause deterioration or ulceration of the cornea. They take more care than they are worth. Many quit wearing them soon after they get them. Actors and athletes are acclaimed for being able to do their stuff with contact lenses, as if the contact lenses make them normal-eyed. It is strange that some eyemen who fit contact lenses do not wear them themselves.

Like glasses, contact lenses fitted for one distance, usually twenty feet, are wrong at every other distance. Eyemen who make big of astigmatism with precision fitted glasses, make little of astigmatism, not bothering to correct it with contact lenses, prescribing only spherical power contact lenses in most cases. Before this they would have found fault with me for ignoring or making little of astigmatism, with my theory and method. Contact lenses are a poor makeshift way of trying to get away from wearing glasses. Contact lens fitters try to give the impression that contact lenses are an ideal improvement over glasses, which they are not. Glasses are bad enough for human eyes; contact lenses are worse.

In writing what I have to say as to the cause of refractive and muscular eye troubles, pains, strains and headaches of children and young people, and why glasses are not scientific for them, I have probably left out some things I could have written, and written some things I could have left out. However, I think I have written enough for the open-minded to turn them against glasses. God help the closed-minded who are in favor of glasses. I wish them luck; they will need it. But I defy anyone to prove that glasses are scientific and right, thereby proving me wrong. No one has ever had to prove that, and no one ever can. The more one tries to prove it, the more he will find out he cannot, thereby proving me right.

The law of optics is, as said before: that glasses do not save eyes; that eyes never get better with glasses; that eyes do not even stay the same with glasses; that all eyes grow worse with glasses; and that all eyes would be better off in the long run if they had not put on their first glasses.

No child or young person can defy the law of optics, wear glasses, and get away with it. It is they who will have to pay the penalty of what the glasses will do to their eyes, and for the misunderstanding of their elders. Children may not know any better, but if I have not written enough for their elders to understand, know better, and do something about it, then there is no hope for the future eye welfare of our present and future generations of children and young people.

I feel that I have only scratched the surface against glasses. I have put it mildly. If I really wanted to call a spade a spade, the words I would use would not be fit to print or to say against them.

I have only scratched the surface giving the possibilities without glasses. They are unlimited, as compared to the possibilities with glasses. The results claimed for glasses are not worth the harm the glasses do to the eyes. Anyone who cannot see this does not want to see it. They want to believe only in glasses. Too bad for the victims who they say have to wear them.

If all eyemen would do as I have done, they no doubt would accomplish even more than I have accomplished alone. Many minds can accomplish more than one mind alone. As of now the many minds

have concentrated on how to better fit glasses for the masses of children and young people.

If I have written enough for the elders to take hold, to keep away from glasses in the first place, to deliberately remove those glasses already worn, discipline them in the use of their eyes in all close work, and watch and wait for their eyes to improve over a period of time, then the present and future generations will have a better eye future than ever before. This is asking very little to accomplish so much. No one will be hurt. All will improve toward normal vision, many fast, some slow, over a period of time.

Life is too short for the masses to let their eyes go the way of glasses, the way they are going. We can do better than that. We can no longer deal in the easy way of glasses. We must deal in our future eye welfare.

Radical and revolutionary changes will have to be made by all concerned. We may not like it at first. Nevertheless, that is what is called for. But when we see how much good can be done for the eyes of children and young people, without glasses being fitted for wear, we will glory in it and forget the easy way of glasses. In fact, we will refuse to prescribe or fit glasses for wear for any child or young person, regardless of the refractive or muscular eye trouble, pains, strains, or headaches. We should not allow any one of them to demand and get glasses. Instead of allowing them to tell the eyeman what they want, the eyemen should tell them what they will have to do, and why.

If all eyemen would do what I have been doing for forty years, no child or young person would be able to get a pair of glasses for wear. Instead of making see or relieving them with glasses for wear, we will prevent, improve, or cure them, by directing them how to use their eyes right, and how not to use them wrong.

If eyemen are going to worry about what will become of them and their practice of fitting and selling glasses to the masses of children and young people, rather than how much more good they can do for eyes, then eyemen are not honest, truthful, and sincere in their eyework. My turning against glasses for children and young people, some forty years ago, did not ruin my practice. In fact, it increased my practice so much that I could tell the greatest success story of any practitioner in this healing art, not only in what I was able to do for eyes, but in volume of patients per day.

Starting from scratch, with my theory and method, I stepped up my one-half-hour corrective measure office treatments to my high mark of 221 in one day, handling thirty patients at one time. I had to increase my office space five times. Since that time I have improved my method, changing from office corrective measures to home corrective measures, which I wished I had done long before. I no longer needed the biggest office in town, and it was better for my patients, who got more out of my corrective measures with less cost and inconvenience. However, that is another story, and possibly too few would care to believe it. But it *is* true, and I have the records to prove it.

If eyemen would use their heads and do some thinking, from the clue I have given herein they could

come up with what I have discovered. It would turn them against glasses for the masses of children and young people as it did me, and the prescribing and fitting of glasses for them would be a thing of the past, and gone forever.

CHAPTER V

EXPLANATORY CHARTS

This sketch, scaled 10 mm. to a foot, shows how wrong and unscientific nearsighted glasses are at every foot, inside of twenty feet, regardless of the Rx, or what is looked at. Note particularly 1 foot, 5 feet, 10 feet, and 15 feet; also the 20 foot distance at which all nearsighted glasses are fitted.

(Chart I)

1 foot	- 20	times wrong
2 feet	- 19/20	times wrong
3 feet	- 18/20	times wrong
4 feet	- 17/20	times wrong
5 feet	- 16/20	times wrong
6 feet	- 15/20 or 3/4	times wrong
7 feet	- 13/20	times wrong
8 feet	- 12/20	times wrong
9 feet	- 11/20	times wrong
10 feet	- 10/20 or 1/2	times wrong
11 feet	- 9/20	times wrong
12 feet	- 8/20	times wrong
13 feet	- 7/20	times wrong
14 feet	- 6/20	times wrong
15 feet	- 5/20 or 1/4	times wrong
16 feet	- 4/20	times wrong
17 feet	- 3/20	times wrong
18 feet	- 2/20	times wrong
19 feet	- 1/20	times wrong
20 feet	-	The distance all nearsighted glasses are fitted
To infinity		

(While the above may not seem to be optically correct to some, it is near enough to give an idea of why nearsighted glasses are wrong and unscientific, especially incases of children, and young people under the age of thirty-five.)

Visiograph

The following graphs are designed according to a new theory and method for eyes, to show the past present and future of any eye or eyes, where the history of the case is known, or the present and future, where the history is not known, but can be assumed, according to experience in the field of eye work.

The graph shows that the more or less bad eyes of the past, present and future, largely and in the most part, are due to the misuse of eyes in-the-beginning, and using glasses as the remedy thereafter, in place of being shown how not to misuse eyes in the beginning, and for want, or need, of a better remedy for eyes in the beginning, and thereafter.

By this graph the designer would allow that glasses might be necessary, in most cases, in middle age and past, but to be best, at and past such age, glasses should not be the remedy, under that age, regardless of the condition. Though some such glasses may be necessary, the graph proves by analyzing cases, according to the lenses prescribed, over a period of time, that all eyes go worse and none get better by their use.

Explaining the graph: The numbers at the top show ages of eyes from age 1 to age 60, by years. The horizontal line, near the middle, is the normal line. The vertical line, near the right middle, at age 40, is the turning point of most all eyes, when, even if they were normal to age 40, they will begin to lose their power to read or do close work.

Below the normal line is Hypermetropia, or farsightedness, as shown by lenses numbered and with plus sign, as found in Dynamic Skiametry and Subjective Test findings, which could be the same, only in a perfect normal eye, otherwise, never the same, even with glasses unless corrected by a method other than glasses.

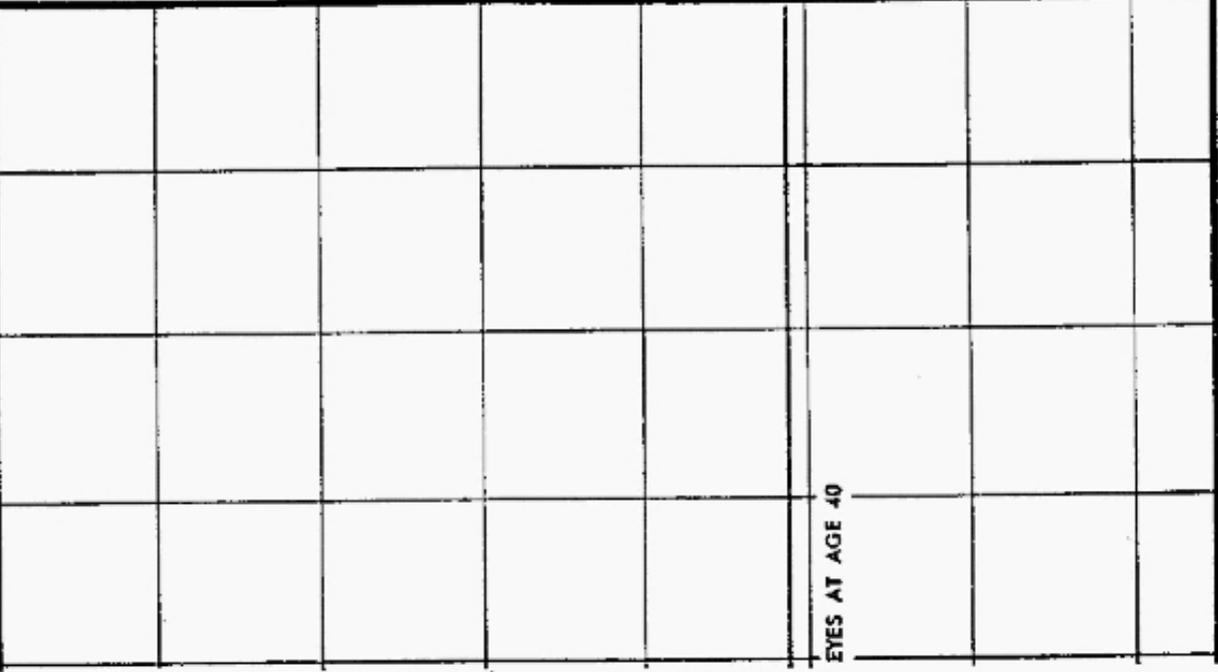

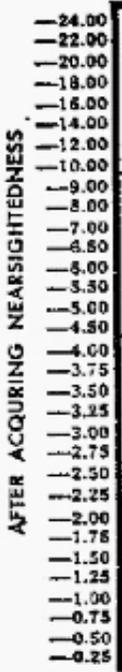

Above the normal line is Myopia, or nearsightedness, as shown by Pseudo Myopia and numbers with minus sign, as found in Dynamic Skiametry or Subjective Test findings, which are never the same, in any such conditions. The words Pseudo Myopia and the numbers show danger in minus lenses and Pseudo Myopia, which leads to Progressive Myopia, a condition known and feared by all eyemen, yet is brought on by the wearing of glasses at a young age, at all distances, that are only near scientific at the distance they were fitted (usually 20 feet) or beyond. Progressive Myopia can also be brought on by the misuse of eyes, even without glasses, but not as high a degree as with glasses. The words Pseudo Myopia mean beginning or false nearsightedness.

Both above and below the normal line the numbers denoting lens powers are spherical, or average power of a combined Rx, including Astigmatism, or can be used for simple Astigmatism. However, Astigmatism is slowly progressive, while Hypermetropia and Myopia, which is combined with it, Dynamically, in most cases, are fast progressive where glasses are worn. So, low degrees of Astigmatism in most cases are ignored in favor of showing the past, present and future of Hypermetropia and Myopia, where the more or less history of the case is known.

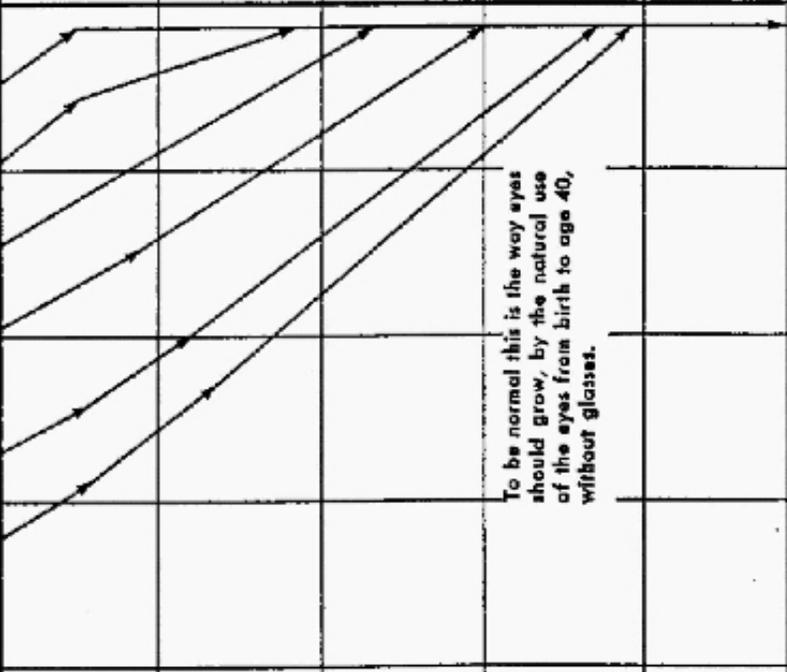

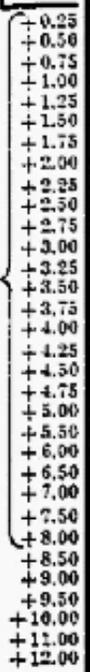

Directions: Obtain copies of prescriptions of all glasses worn, and at what age, to date, or at least, if possible, the first pair and last, and at what age obtained. Mark a dot where the Rx space and age meet, for every change that has been made. Then draw a line from the normal line to first dot, then from dot to dot. Thus it will be seen how fast and how far the eyes have gone from the normal line. So-called normal visual acuity with glasses should be classed as artificial normal visual acuity. While it is easy to believe that glasses save eyes and hard to understand that they don't, the graph shows that glasses take eyes farther and farther from the normal line, and do not save eyes.

This graph was designed under a complete new theory and method for eyes, discovered some forty years ago, carried on carefully and quietly through these years, in private practice, on thousands of cases, by the discoverer, J. J. KENNEBECK, O.D., KANSAS CITY, MO.

PRESBYOPIC TURNING POINT OF EYES AT AGE 40

This is how farsighted eyes would grow more farsighted, from wearing farsighted glasses.

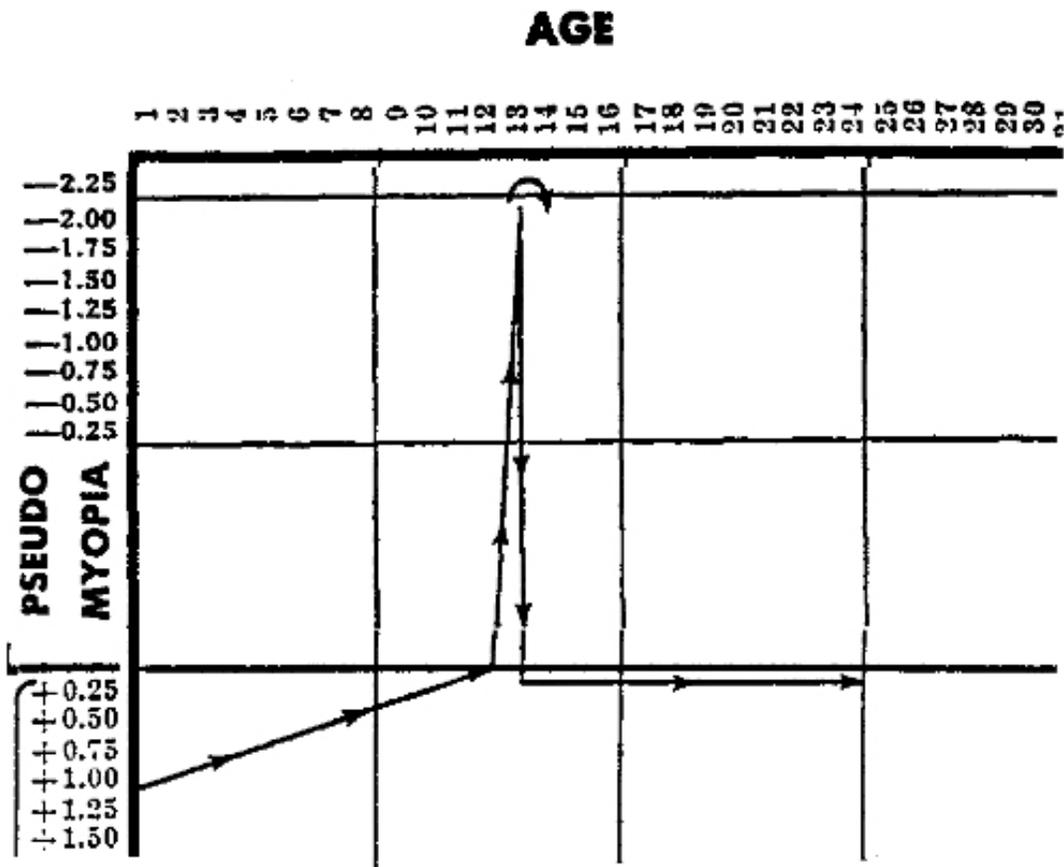

THIS IS THE CASE OF JOHN R.

His vision checked normal for seven years, up to age 13, when suddenly he went nearsighted (minus 2.00 diopters), as described in my script, from collecting stamps and coins, lying on his stomach on the floor, with no more light than that which came from the television screen in an otherwise darkened room. Caught in time, his vision returned to normal within two weeks and has held ever since, and without glasses. He had to stop at once that which caused his nearsightedness.

Exactly the same thing is happening to millions of other children and young people under the age of thirty-five. Caught in time, all the millions can be helped as John R. was helped.

While I have shown the case of John R. starting out with dynamic skiametry findings of plus 1.00, no doubt he was born with plus 2.00 to plus 4.00 diopters. However, the lines shown should serve the purpose. Any and all cases could be similarly charted on the graph, depending on the findings, as was the case of John R. All such cases started out with plus, which is natural, and sooner or later changed into minus, which is unnatural, meaning that they changed from farsightedness into nearsightedness. Then all cases grow progressively worse from there unless they stop all bad eye habits and never resort to nearsighted glasses.

CHAPTER VI

MYOPIA EXPLOSION

These are questions asked over a period of forty years about the cause of myopia (nearsightedness) in children and young people, and why glasses are a poor and unscientific remedy for them, with answers according to the author's own theory and method for eyes.

They may come as a shock to those who believed otherwise; it also came as a shock to the author when he discovered it. Nevertheless it is the truth, whether we like it or not.

Q. WHAT IS MEANT BY MYOPIA EXPLOSION?

A. It means that there are more cases of myopia than ever before. Up to twenty-five years ago only a few in every thousand children and young people were myopic. Today it is over ten in one hundred, and getting worse every year. It will go to fifty or more per hundred, if something is not done about it.

Q. ARE CHILDREN BORN WITH MYOPIA?

A. No. Their myopia is acquired sooner or later. No one can be born myopic. But for the sake of argument, just suppose one was born with one diopter of myopia. Later on he has two, three, five ten, and up to twenty-five diopters of myopia. Where did he get the increased myopia? He was supposedly born with only one diopter. Even if one was born with myopia, glasses are not the scientific remedy.

Q. ARE NOT MYOPIC EYEBALLS TOO LONG?

A. No; neither are hyperopic (farsighted) eyeballs too short. Eyeballs could not be as long or as short as they would have to be, in more or less high diopter myopic or hyperopic eyes. Even if they were, glasses are not the scientific remedy.

Q. IS MYOPIA HEREDITARY?

A. No. Only hyperopia might be hereditary. It would make no difference if a parent, grandparent, or uncle, or aunt were or were not myopic. Each and every one who is myopic had to acquire it himself. Even if myopia were hereditary, glasses are not the scientific remedy.

Q. WHAT IS MYOPIA?

A. Myopia is a locked over-convexity of the refractive media of the eye. Hyperopia is an undeveloped refractive media of the eye. All myopic eyes were once normal or hyperopic.

Q. HOW IS MYOPIA ACQUIRED?

A. Most cases of myopia can be traced to misuse and abuse of the eyes as heretofore described in detail. Some cases can be traced to watching television at too close a range.

Q. COULD THERE BE OTHER CAUSES OF MYOPIA IN SOME CASES?

A. Yes. Myopia can also be acquired from getting unnecessary myopic glasses for reasons other than real refractive eye trouble. This is called malingering, fooling parents and obtaining glasses that are not needed. Normal and some hyperopic eyes can see better with myopic glasses, but they should not be allowed to. As soon as the unnecessary myopic glasses are worn long enough, the eyes will no longer be normal, or hyperopic, as they were before. They will be myopic from then on, and will go into progressive myopia. This would not have happened if they had not put on the unnecessary myopic glasses in the first place. It is surprising how many malingering cases there are. Myopia can also be acquired from wearing sunglasses.

Q. WHAT DOES THE WORD "BOOKWORM" COVER?

A. The word "bookworm" covers the reading of too many books, newspapers, magazines, prayer books in church, comics; writing, drawing, sketching, coloring, keeping stamps and coins, picking at fingers, manicuring the nails, boys making model airplanes and boats, girls cutting out paper dolls, crocheting, knitting, sewing, etc., all incorrectly.

Q. WHAT IF THEY COMPLAIN OF PAINS, STRAINS, OR HEADACHES?

A. Most of them are caused by the same bad eye habits, in any and all close work, as previously described. Often they are the forerunner of myopia to follow, if they keep up the bad eye habits. There are also other causes, such as exposure to fumes of fresh paint, varnish, gas or systemic upsets, for which glasses are certainly not the remedy. Those who wear glasses for them soon have them with the glasses.

Q. IF CHILDREN AND YOUNG PEOPLE DID NOT MISUSE AND ABUSE THEIR EYES, OR FEIGN EYE TROUBLE, AS DESCRIBED, WOULD THERE BE FEWER CASES OF MYOPIA, OR COMPLAINTS OF PAINS, STRAINS, OR HEADACHES, AND THEREFORE NO GLASSES WORN BY THEM?

A. That is true, and their eyes would tend toward normal.

Q. WHY ARE GLASSES UNSCIENTIFIC FOR THEM?

A. Glasses are unscientific for them because the glasses create more of the same problem for which they were prescribed and worn. There is no end to the progression of myopia with myopic glasses. It will continue up to and even past the age of forty.

Q. HOW DO MYOPIC GLASSES CREATE MORE OF THE SAME PROBLEM FOR WHICH THEY WERE PRESCRIBED AND WORN?

A. This and the answer to the next question alone should be enough to turn anyone against myopic glasses. All myopic glasses are fitted at one distance, usually twenty feet. The glasses are wrong at every other distance. It would be better to wear no glasses at all than to wear wrong glasses. No lens can be made to fit the eyes at all other distances. No one looks through his glasses at exactly twenty feet all the time. All eyes look at many distances, from near to far, in all directions. Myopic glasses are habit-forming at twenty feet and beyond. Few use their eyes beyond twenty feet as much as they do inside of twenty feet. At every foot inside of twenty feet the glasses are many times worse. At TEN feet the glasses are TWICE wrong; at FIVE feet the glasses are FOUR times wrong; at ONE foot, where all close work is done, the glasses are TWENTY times wrong. This is arrived at by dividing the footage, or distance eyes look at, into twenty feet, where the glasses are fitted. The same reasoning goes for contact lenses, which are worse than glasses. Better read this and the next answer again and again. No one can deny these facts in order to justify the wearing of myopic glasses.

Q. CANNOT EYES COMPENSATE, THROUGH MYOPIC GLASSES MADE FOR TWENTY FEET, TO SEE AT ALL OTHER DISTANCES?

A. Yes. Eyes can compensate, as per the question, as long as they are young enough to do it. But, I must warn you that eyes cannot compensate, as per the question, WITHOUT BEING HURT. It is the compensating, through myopic glasses fitted for twenty feet, that brings on progressive myopia, locking the refractive media of the eyes into more and more over-convexity.

Q. ARE NOT BIFOCALS PRESCRIBED IN SOME MYOPIC CASES, IN AN ATTEMPT TO OFFSET COMPENSATING FOR CLOSE WORK?

A. Yes, but bifocals are a feeble attempt. However, prescribing bifocals does prove that it is bad for eyes to compensate for nearsightedness through myopic glasses fitted for twenty feet. But glasses, particularly of the myopic variety, are bad at ALL distances inside of twenty feet. That is why ALL myopic cases grow progressively worse, even with bifocals.

Q. THEN EYES CANNOT GET BETTER, AND MUST GO WORSE, WITH MYOPIC GLASSES?

A. Yes, in ALL cases. They ALL grow worse every year thereafter. If one does not seem to have gone worse, the glasses were over-fitted the time before.

Q. THEN THERE ARE NO CASES THAT MIGHT BE EXCEPTIONS?

A. That is true. There are no exceptions.

Q. THEN NO CHILD OR YOUNG PERSON SHOULD WEAR MYOPIC GLASSES?

A. That is true. Wearing myopic glasses prevents improvement. The very nature of the glasses is to artificially and temporarily make see or relieve, never to improve or cure. Nature never intended people to wear myopic glasses. Nature intended other means to help improve or cure myopia.

Q. CAN PEOPLE IMPROVE OR CURE THEMSELVES WITHOUT MYOPIC GLASSES?

A. Yes, providing they are disciplined in the use of their eyes and never wear myopic glasses.

Q. HOW LONG DOES IT TAKE FOR MYOPIC EYES TO IMPROVE OR CURE WITHOUT MYOPIC GLASSES?

A. It takes a year or longer, depending on the case. But improvement will begin at once, the minute one stops all harmful eye habits. As for a quick cure in bad cases, there is no such possibility. Myopia is very much like diabetes. Once a diabetic, one always has a tendency toward it unless he lives right. Once stricken with myopia, one always has a tendency toward it thereafter unless he lives right. This applies even to the mildest cases. Age and time help to improve myopia, but only if they ease up in their bad eye habits, and never wear myopic glasses. Rather than to stress what can or cannot be done for cases already stricken with myopia, it is more important to prevent new cases from acquiring myopia. Then we would not have such severe advanced cases. Otherwise, the mild cases of yesterday and today will become the severe progressive cases of tomorrow.

Q. HOW SHOULD PEOPLE BE DISCIPLINED IN THE USE OF THEIR EYES?

A. They should be made to stop all unnecessary close work. What close work they think they have to do should be done under good incandescent light, looking up and away often. They should blink and squeeze their eyes with their eyelids often.

Q. ARE THERE ANY OTHER THINGS THEY SHOULD NOT DO?

A. Yes. They should never wear sunglasses, or look through binoculars, telescopes, opera glasses, or field glasses, or try on any glasses.

Q. WHY ARE SUNGLASSES OR TINTED LENSES BAD?

A. They are bad because they dilate the pupils of the eyes, when eyes need sunshine and light to contract the pupils. The smaller the pupils the better eyes see and the safer the future. Dilated pupils are one of the first signs of myopia to follow.

Q. WHY ARE BINOCULARS, TELESCOPES, OPERA GLASSES, AND FIELD GLASSES SO BAD?

A. They are bad because the optical power of the lenses in them are worse than glasses, particularly to myopic eyes.

Q. THEN DILATION OF THE PUPILS, FOR AN EYE EXAMINATION, IS ALSO BAD?

A. Yes, it is bad and totally unnecessary. It takes skill and a knowledge of eyes and optics to examine eyes without dilation.

Q. CAN CHILDREN AND YOUNG PEOPLE GET ALONG WITHOUT MYOPIC GLASSES?

A. Yes, and their eyes could gradually return toward normal, as my own eyes did, after I acquired myopia at the age of twelve.

Q. WHAT IF THEY SQUINT TO SEE WITHOUT MYOPIC GLASSES?

A. There is no harm in squinting. It helps the eyes improve or be cured. Those who wear glasses to keep from squinting soon squint with the glasses.

Q. ARE NOT SOME CASES BLIND WITHOUT MYOPIC GLASSES?

A. No. None are blind without their myopic glasses. They only say they are blind without them. Only blind people are blind, and they cannot see even with glasses. Myopic cases may not see small things, or signs farther away without their glasses, but otherwise they can see well enough to get along, until they improve and begin to see better.

Q. CANNOT CHILDREN AND YOUNG PEOPLE WEAR MYOPIC GLASSES PART-TIME, SUCH AS IN SCHOOL, AND NOT GROW WORSE?

A. No. There is no halfway in myopic cases. If they wear myopic glasses all the time, or even part-time, they must grow worse. If there are some things they cannot do without myopic glasses, they cannot do them until they improve enough to do them. One must persevere and do the best they can without glasses. If one left his myopic glasses off for a day, a week, a month, or a year, and then put them on, even for a minute, he would ruin all the good he had done by going without his myopic glasses. Eyes are quick to take hold, through myopic glasses, and to be what the myopic glasses make them.

Q. HOW CAN THEY GO TO SCHOOL AND LEARN WITHOUT THEIR MYOPIC GLASSES?

A. Many myopic cases go to school and learn without myopic glasses. Not all myopic cases wear glasses.

Some parents refuse to allow their children and young people to wear glasses. They have found ways and means to keep them from wearing them. Children and young people can get their education and save their eyes at the same time, by using their eyes in the right way. If they do that, sooner or later the eyes will improve and they will find things easier and better. Not one of them has to ruin his eyes to get his education. With the proper cooperation of teachers and school nurses, all students can go through school without myopic glasses. A student recently graduated from the University of Chicago with the highest honors. He was totally blind.

Q. HOW CAN TEACHERS AND SCHOOL NURSES COOPERATE TO HELP MYOPIC CASES?

A. Teachers can write larger on the blackboard, keep the blackboard black, and see that there is no glare on it. They can allow myopic students to sit in or near the front row. They should not give students so much homework to do. Students' eyes become weary and bleary from too much homework, with or without myopic glasses. School nurses can make screening tests of students' eyes, but should not suggest or insist that the student get glasses. Teachers should spend a little time every day in every class, in all schools up to university level, teaching students how to use their eyes right and how not to use them wrong. Fast and furious overeducating is the cause of too many students going myopic. It would be better to be the poorest student with the best eyes than to be the best student with the poorest eyes. Eyes should come first.

Q. THEN PERFECT VISION, WITH MYOPIC GLASSES, DOES NOT MEAN PERFECT EYES?

A. That is true. Strong glasses do not make strong eyes. Myopic eyes are already too strong. Only hyperopic eyes are weak, and hyperopic glasses make them weaker. Myopic glasses over-develop the refractive power of the eyes, as previously explained.

Q. THEN MYOPIC EYES ARE TOO STRONG, AND HYPEROPIC EYES ARE TOO WEAK?

A. That is true, and they grow more so with glasses.

Q. HOW BAD CAN EYES GROW WITH GLASSES?

A. Very bad. Myopic eyes can go as bad as thirty diopters, with glasses, as compared to eight diopters for hyperopia. The naked visual acuity can go as bad as 20/400, or worse, with myopic glasses. Wearing myopic glasses through life could lead to blindness from detachment of the retina, conical corneas, myopic cataracts or glaucoma, at middle age or past. Myopic cases are more subject to these conditions than other cases.

Q. WILL MYOPIC CASES NOT GO THAT BAD WITHOUT GLASSES?

A. No, they will not go that bad without glasses.

Q. IS HYPEROPIA AS BAD AS MYOPIA?

A. No. All eyes are born with more or less hyperopia. This is natural. They develop toward normal by the natural use of the eyes as they grow older. If they resort to glasses, the glasses stop their natural development. It would be better for eyes to be more or less hyperopic than to be even one diopter myopic. Hyperopia is not nearly as bad as myopia.

Q. THEN CHILDREN AND YOUNG PEOPLE WOULD BE BETTER OFF IN THE LONG RUN, REGARDLESS OF THE EYE CONDITION, IF THEY HAD NEVER PUT ON THEIR FIRST GLASSES?

A. That is certain. They have no future, with glasses, but to grow worse.

Q. THEN WHY ARE GLASSES PRESCRIBED FOR THEM?

A. That is a good question. Professional ethics do not permit me to answer, but I have records to show that all cases grow worse with glasses and improve without them. It stands to reason that this is so. Since I am opposed to glasses for children and young people, it is not up to me to answer this question.

Q. WHY CANNOT ALL THIS BE BROUGHT TO PUBLIC ATTENTION?

A. That is another good question, but difficult to answer. Again I have to hide behind professional ethics. It is bad enough for me to say what I do against glasses. I can only say that the old tradition of glasses has taken such a hold on the masses, that anyone who raises his voice against glasses is branded as a quack. I know of no media by which all this could be brought to the attention of all concerned. One would have to ask elsewhere for the answer to this question.

Q. THEN THERE IS NO AUTHORITY WITH THE POWER TO DO SOMETHING ABOUT IT - TO FORCE IT ON ALL CONCERNED, SUCH AS PARENTS, TEACHERS, SCHOOL NURSES, AND THE CHILDREN AND YOUNG PEOPLE THEMSELVES?

A. Not that I know of. I only wish there were. Something could be done about it if and when enough interest in these questions and answers is shown. It is strange that the masses so strongly believe in glasses and that they are skeptical of anyone who raises his voice against them. Eyeglass wearers, who are not qualified to be skeptical, would scoff at, deride, and ridicule anyone opposed to glasses.

Q. WHAT ABOUT OTHER EYE CONDITIONS NOT MENTIONED HEREIN?

A. Let it be understood that other eye conditions cannot be included herein. This deals mostly with myopia. Information on all other refractive and muscular eye conditions can be furnished on request, by written questions. Let it also be understood that adult eye conditions are not included herein. It is too late for most of them. Their eyes are more or less set in their refractive eye trouble. While most of them have

to resort to glasses, they should be fitted with the weakest lenses possible, and wear them no more than necessary. Their glasses should never be on when they could be off. The more they go without their glasses, the better their eyes will be and the longer their glasses will last, without changing them so often.

Q. THEN GLASSES SHOULD BE ALLOWED FOR ADULTS, NOT FOR CHILDREN AND YOUNG PEOPLE?

A. That is correct. Just because adults have to resort to glasses is no reason to think and believe that children and young people have to. There is no comparison. While an adult's eyes are more or less set in their refractive eye trouble, as said before, children's and young people's eyes are flexible and in the process of development. The eyes of children and young people will respond to discipline, with or without corrective measures, while the adults will not.

Q. IS THERE A SECOND BEST WAY FOR ALREADY ADVANCED CASES OF MYOPIA TO HELP THEM TO KEEP THEIR EYES THE SAME, OR FROM GOING WORSE?

A. Yes. First have minimum - or less - prescription glasses for emergency use only, such as driving, or for whatever might be important. Then wear the glasses as little as possible otherwise. Stop all unnecessary close work. What close work one thinks he has to do, should be done without glasses if possible, under good incandescent light, looking up and away often. If the ease is so severe that one cannot do close work without glasses, he should have special half-power glasses for close work, or bifocals. From then on, do not change the glasses, unless the power of the lenses can be reduced. Be checked for that every one or two years.

This is not a solicitation of patronage. It is intended to help those who care to help themselves. However, there are corrective measures for the already severe advanced cases that may need help. This could only be done in person, and after an eye examination under the proper theory and method. But even such severe advanced cases can help themselves somewhat by quitting their bad eye habits and deliberately discarding their glasses permanently, even without correct measures.

This is a **WARNING** against myopic glasses for children and young people. There is nothing in the healing art that could look so right and be so wrong as myopic glasses for them. They are the ones who must pay the penalty, as they grow older, for what was done for them when they were younger. Innocent and unsuspecting as they are, they will wear any glasses that are put on them, with never a complaint as to whether the glasses are fitted right or wrong. Real refractive eye trouble begins then and there.

If all concerned with the eyes of children and young people would heed the warning given herein there would be no new cases of myopia, and therefore no glasses to be worn. Cases already stricken could be improved or cured. Symptoms of pains, strains, and headaches would be no more. All would have better eyes through life. Loyalty to the old tradition of glasses for the masses will not save the eyes of the present and future generations. No one has ever had to prove, or ever could prove, that myopic glasses save the eyes of children and young people. I should not have to prove further that they do not. If what I

have had to say is not enough proof, then there is no hope for their eyes.

Most cases that do what is called for herein will notice and admit improvement or cure. However, there are some who will hold back. Due to their loyalty to the old tradition, to save face and not be proven wrong for having worn glasses, they will insist that they notice no improvement in seeing or feeling better. In fact, some will declare that their eyes have grown worse. They love their glasses, and what they think glasses do for them, for secret reasons of their own. Such unfair opposition makes it hard to prove to the world that glasses do not save eyes; that eyes never get better with glasses; that eyes do not even stay the same with glasses; that all eyes grow worse with glasses; that all eyes would be better off, in the long run, if they had never put on their first pair of glasses. Such is the law of optics and eyes, whether we like it or not. Time will prove it to be true. No one can defy the law of optics and eyes and get away with it.

It took a Civil War to free the slaves of the South. It will almost take a war, or at least legislation, to free children and young people from becoming slaves to glasses. This is the only way I know to try to arouse parents to turn against glasses for the masses of children and young people. They may have refractive eye troubles that they brought on themselves unknowingly and innocently, but glasses are only a poor makeshift remedy. They need more than glasses can ever do for them. This is about all I can do, at this time, until parents do their part.

CHAPTER VII

CHALLENGING THE HELMHOLTZ THEORY

It is about time someone protests against the praise, honor, and glory given Helmholtz, on his theory of accommodation of the human eye.

As Tscherning violently disagreed with the Helmholtz theory then, I violently disagree with it now. I challenge all who believe the Helmholtz theory of accommodation to give some thought as to whether or not it is even reasonable to believe.

It is not that another theory of accommodation would change eye work as it is being done today, but it could lead to a new understanding of refractive and muscular eye troubles, and might improve the eye work of today and tomorrow. It did this for me over the last forty years.

The crystalline lens of the human eye has little or no elasticity in the first place. Therefore, it could not be the media of accommodation in the second place. Certainly it does not have enough elasticity to focus the human eye, instantaneously, as fast as I can accommodate my own eyes from far to near and near to far. Yet we know that the human eye does have the ability to accommodate instantaneously, for any and all distances.

Then the question arises - if the crystalline lens is not the media of accommodation, what is it there for, and what is the media of accommodation???

The crystalline lens is the core of the eyeball, suspended taut in place in its capsule by the suspensory ligaments, which in turn are connected to the circular ciliary muscles of accommodation. Instead of the crystalline lens becoming more or less convex, as per Helmholtz, under accommodation, it becomes held more or less taut in place, under accommodation.

Under the Helmholtz theory, the crystalline lens would be held less taut in place, and of its own weight it would sag or tip, instead of becoming more or less convex. Its curved surfaces, having a power of 16 to 19 diopters, are more or less neutralized by the curvature of the humors, making the power of the crystalline nil and useless as a refracting media. As a refracting media, eyes could do without the crystalline lens, if internal tone and pressure were not lost in its removal. Suspended taut in its place, it serves as a solid to steady the action of the circular ciliary muscle, and to help keep the eyeball round.

In the act of accommodation, as I see it, the circular ciliary muscle acts in "shoelace" fashion, contracting in itself, drawing the crystalline lens taut and at the same time, making the cornea more or less convex, thereby making the cornea the media of accommodation, instead of the crystalline lens. It has to be that way; it cannot be any other way. At least that way is more believable than the old Helmholtz theory of accommodation. But there is more to say about the cornea, and its power and action under accommodation.

The cornea has more than enough power to do all the focusing for a normal human eye. It is so powerful that it bends all rays, incident on the cornea, directly through even a pinpoint pupil, straight on through the aqueous humor, the crystalline lens and the vitreous humor to the retina. It must be remembered and kept in mind that the point of reversal takes place in the pupil.

Considering a pinpoint pupil, the anterior surface area of the crystalline lens is so small and neutralized by the aqueous humor, that it could have little or nothing to do with refraction. That alone cuts the power of the crystalline lens in half. Then also, the incident and emergent rays pass through the curvatures of the crystalline lens at an almost perfect right angle to its curvatures, on their way to the retina, without being refracted by the crystalline lens, and just as if the crystalline lens was not there.

In the act of accommodation, the cornea becomes more or less convex by the action of the ciliary muscle. The act is so minute that it is not detectable, even with the ophthalmometer. It should be realized that the eye being examined, while looking into the aperture of the ophthalmometer, is under accommodation for the distance it is looking. This gives the corneal curvature under accommodation at that distance. If it were possible to take the corneal curvature with the ophthalmometer while the eye was looking at infinity, it might show less corneal curvature, depending on the type of eye being examined. While there may not be very much difference, this could prove that the cornea is the media of accommodation. I can accommodate either one of my eyes at will. My vision blurs, and I can actually feel the action of the ciliary muscle making the cornea more convex. I can accommodate so strenuously that the object I look at shakes, meaning that my eyeball quivers, but only in the horizontal, as in nystagmus. If I force my accommodation with both eyes together, my vision blurs up to a certain point; then my eyes turn inward, and I see blurred and double. If I then ease up a little in my over-accommodating at will, I still see blurred, but single. If I ease up all the way, I see clear and single.

In my over-accommodating at will, with one eye or both, I am actually making my eyes nearsighted. This means that with my naked eyes, I would see blurred. If I placed a minus lens before my eyes, I would see clear. Doing this under the Helmholtz theory of accommodation, I would be forcing my crystalline lens to bulge into becoming more convex by its own supposed elasticity. If I believed in the old Helmholtz theory of accommodation, I would not dare do that with my own eyes. Not believing in it, and believing in the cornea as the media of accommodation, I do not fear doing it, and overdoing it, if I please, as a matter of experimenting with my own eyes. Since the crystalline lens has little or no elasticity, some other media has to have a lot of elasticity to perform the instantaneous act of accommodating. That other media can only be the cornea. No other media could have such flexibility and elasticity.

Under the old Helmholtz theory, a farsighted eye would mean a lack of convexity of the crystalline lens, and a nearsighted eye would mean an over-convexity of the crystalline lens. This is not even reasonable to believe, but we know it has to be something. If the cornea was the media of accommodation, a farsighted eye would lack convexity of the cornea, and a nearsighted eye would mean an over-convexity of the cornea. That is more reasonable to believe. On close observation of the corneas, one will find that farsighted eyes have a shallow cornea and anterior chamber, while nearsighted eyes have an over-convex cornea and more anterior chamber, with usually large pupils, a glassy and starry-eyed look, and a bulgy eyed appearance.

Under the Helmholtz theory, presbyopia is supposed to be the physiological hardening of the crystalline lens. Since the crystalline lens has little or no elasticity, this theory of presbyopia also is not even reasonably believable. With the cornea being the media of accommodation, presbyopia has to be the loss of power or action of the ciliary muscles, or loss of flexibility of the cornea, or both. It seems that it has to be a loss of power of the ciliary muscles. It is not reasonable to believe that the cornea could have such a fault, or have anything to do with it.

Going beyond what is or is not the theory of accommodation, the crystalline lens and ciliary muscles have another duty to perform. They not only serve to help keep the eyeball round, but all extrinsic muscles oppose each other through it. Without them, the extrinsic muscles could pull the eyeball out of round. The crystalline lens and ciliary muscles could perform such duty better with the cornea being the theory and media of accommodation, than with the old Helmholtz theory.

Any theory of accommodation would be hard to describe. If one would imagine the crystalline lens as a solid suspended in place, the ciliary muscles as a muscular ring, and the extrinsic muscles attached to it under tension, one would have a better picture of the cornea as being the media of accommodation.

One has to have a strong imagination to picture the act of accommodation under the old Helmholtz theory. One may not be able to catch the cornea becoming more or less convex in the act of accommodation, but that does not mean that anyone has ever caught the crystalline lens becoming more or less convex, in the same act. What proof is advanced, in an attempt to prove the crystalline lens as the media of accommodation, could be credited to the act of the cornea. In fact, as stated previously, the act of accommodation in the human eyes is so minute as to be beyond detection, whether the media be the cornea or the crystalline lens. However, in either case it takes the action of the ciliary muscles, which in normal eyes should be as active as the hairspring of a watch, to activate accommodation. Whatever the media of accommodation, it has to be fast and instantaneous. In any case, as I see it, it can only be the cornea.

With the theory of the cornea being the media of accommodation in mind, I was able to go even farther into the cause and condition of all refractive and muscular eye troubles, especially in cases of children and young people, and do something about it. This I could not have done under the old Helmholtz theory. If others would do as I did and do some thinking, they might run into the same thing. If they did, they would find it as revolutionary as I did.

Right now I only wish to establish a change in the theory of accommodation, from that of Helmholtz to what it should have been all these years. Once and for all, I would like to see the old Helmholtz theory of accommodation thrown overboard, and establish the cornea as the media of accommodation of the human eye. In doing that I would discredit Helmholtz, as he should have been discredited years ago for holding back advancement in thinking, in eyework, for all these years.

CHAPTER VIII

CORRECTIVE MEASURES AND OTHER FACTS

I have said that corrective measures can only be determined after an eye examination, under the proper theory and method. From what I have said in my book, many eyemen could reason out what the corrective measures might be and use whatever they want to. If they wish to know what I use, they would have to contact me. However, if enough interest is shown, I might write up what I do in most ordinary cases. But I must insist that the main thing to do is to DISCIPLINE children and young people in the use of their eyes and never prescribe glasses for wear. Corrective measures are secondary.

It is very much like the vaccine for the prevention of polio. They do not say, and very few know, what is in the vaccine. It is only known that it is necessary to have the shots to prevent polio. That is true of other shots, and medical prescriptions also. Patients do not know what is in them, yet they accept them.

It is the same with corrective measures for the eyes of children and young people. It is strange how all believe in and accept glasses as a remedy without question, although patients know nothing about them. Eyemen say to the patient, "You Need Glasses," without explaining just what kind of lenses will be used, what is the prescription, and why, or what glasses will and will not do to the eyes.

Corrective measures are corrective measures-whatever is necessary for the treatment of whatever the case might be. Just what they are and for what case (and there are too many types of cases), cannot be included in my book. While the vaccine is the same for all in the prevention of polio, corrective measures are different for different types of eye cases. The case would have to be known before the type of corrective measures could be determined.

ANOTHER MOST SEVERE CASE

I recently had a case whom we shall call Jack C., age sixteen. Visual acuity was a poor 6/200, dynamic skiametry a hazy reflex of high minus. He had been wearing minus 18.00, minus 1.00, axis 180-, for a year, and had worn glasses for seven years. With this prescription he had only poor 20/200 vision. It was a case of high amblyopia in both eyes. With the glasses he could hardly read #6 type at three or four inches. His too-strong lenses gave too little improvement in seeing.

During my examination I found that he could do as well with his own eyes without glasses. Therefore, he had been misfitted with the above lenses, which made his bad eyes even worse. But because he had sub-

normal amblyopia, it was thought by the patient, the school nurse, and his eyeman that he must have some kind of glasses.

Jack was a dull sort of person, one who would be difficult to examine; it would be equally difficult to arrive at what lenses should be prescribed. He must have been even more difficult at the age of nine, when he got his first glasses. He had misused his eyes for too long before that, and no doubt he had been misfitted at that time, and since. Even now, he stated that he could see better through his brother's thin-lensed glasses than he could with his own thick-lensed glasses. Jack was a poor reader. About the best he could do was the three- or four-letter words, holding the reading three or four inches from his eyes, and his eyes hurt when doing close work with his glasses.

I do not claim that corrective measures will help him, but I do claim that he would not be hurt, and could be helped, by taking his glasses away from him, which should have been done long before. It is too late now to do much for him, and only time will tell.

The point I wish to make is that it would have been better to have done nothing than to prescribe misfitted glasses.

CASE OF RICHARD S., AGE SIXTEEN

Richard S. was examined in 1953 as follows: Vision right eye 20/200; left eye 8/200. Dynamic skiametry test: right farsighted structural astigmatism plus 4.50, axis 105 degrees; left eye, nearsighted minus 4.50. This case had two radically different eyes; he had high diopter farsighted structural astigmatism in the right eye, and high diopter nearsightedness in the left eye.

At the age of six, when entering first grade, the school nurse was not satisfied with the results of his vision test. She asked that he be taken to an eye specialist, which was done. After a lengthy examination, the specialist reported that Richard's eyes had been stabbed by instruments at birth, and most of his vision was gone. He was fitted at once with strong glasses, as the parents were told that it would not be safe for him to cross the street with his poor vision. Richard did not like the glasses, and he was taken to other eye doctors, always hoping they would find some new help. They were always told the same thing; that his case was hopeless.

When Richard reached the age of sixteen, a new friend told the parents about having her vision restored under my theory and method. Richard was brought to me. I analyzed his case, testing each eye separately as to its condition, took his glasses away from him, and started corrective measures. He reported faithfully, with full cooperation. I had to treat each eye separately, and he began to show improvement. Later when he was called up by the army for his physical examination, he passed his vision test. He had no trouble getting his driver's license. Without glasses, he received his Masters degree in education with all of the attendant reading and studying.

.

Practically all of the above history was taken from a testimonial letter written by his mother in January, 1967, wherein she said she was grateful for his good eyes, and the fact that they did not give up when they were told that his vision was almost entirely gone, and nothing could help his eyes. Most of all they were grateful to me for what I was able to do for him.

I do not say that I made his eyes normal, but I did make it possible for him to live and get his education without glasses, and I kept his eyes from going the way they would have gone with glasses.

A SEVERE CASE OF MUSCULAR IMBALANCE

Another severe case concerns a woman patient in her fifties, from Sioux City, Iowa. She and her husband were on vacation in California, where they heard of my work. They stopped to see me on their way back.

Her case was one of high 40 degree vertical muscular imbalance, called right hypertropia, combined with some estropia. This means that the right eye actually turned up and inward, while the left eye was straight or, *vice versa*, the left eye turned down and inward, while the right eye was straight. A degree or two of such a condition is bad enough, but in her case it was 40 degrees.

She was wearing 40 degrees of prism, fitted by a well-known specialist at a well-known State University clinic eight years before. Her glasses were so heavy the nose pads made depressions deep into the bridge of her nose. She was highly nervous, in poor health, and her family thought she was becoming a mental case. She had another pair of prism glasses, slightly stronger, fitted four years before by the same specialist. I have both pairs.

I deliberately removed her prisms, giving her just ordinary plano bifocals to be used only for close work, totally ignoring the muscular imbalance. I advised her that she would have to live with the imbalance, closing one eye, if necessary, to eliminate any double vision. She did as I advised.

Six months later she was back for a checkup. She was a new person in most every way; she could do close work and driving and was in better health. Her family no longer thought she was becoming a mental case. She still had some muscular imbalance, but was much improved. Again, six months later, she was back for another checkup, still going strong and more improved.

I do not mean to say that I cured her severe muscular imbalance (tropia), but I did make it possible for her to live, and be happy, without the 40 degree prism lenses. The prisms she was wearing not only kept her from improving, but created more of the same for which they were prescribed.

A WORD FOR THE SCOFFERS

No one can truthfully scoff at what I have written against glasses for children and young people under the age of thirty-five. Untruthful scoffers will do anything to try to justify the wearing of glasses, in order to save face and not be proven wrong for what they have been doing all these years. Scoffers will say that fifty thousand eyemen and millions of eyeglass wearers, in our country alone, cannot be wrong. Scoffers will say that if there was another way-without glasses-they would have known it long ago. Scoffers will insist that child behavior depends on vision training, meaning prism orthoptics and glasses, when all the child needed was DISCIPLINE in the use of their eyes no prism orthoptics, and no glasses. God help the scoffers, for they know not what they do.

It has been said that about 90 per cent of the people are honest, but this may not be so in the instance of eyes and glasses. It has also been said that this is a country of free speech. That is probably true as long as one is in favor of glasses for the eyes, but not so true if one raises his voice against glasses. Scoffers in favor of glasses for the masses would crucify the one who raises his voice against them. However, if there are enough honest people who will understand and do what I have done about it for the past forty-four years, in thousands of cases, then we will not have to worry about the few scoffers. They will have to come around sooner or later.

Scoffers should be skeptical of glasses, instead of otherwise. But scoffers will say they do not have the time and do not want to bother with anything but glasses. Little do they understand what they say. A pair of human eyes is priceless. The time will come when scoffers will wish they had listened to reason and had done what they should have done at a younger age.

WHAT I WOULD ADD

The "hippies" and "yippies" are not the only ones who put on modern and antique glasses for effect. Many normal people, particularly the male species, do the same, even children and young people. If all such glasses had plano lenses they could neither help nor hurt the eyes, but none of them are plano lenses. Practically all of them are prescription lenses of more or less power. They do not know what they are doing to their eyes. Let them grow beards, mustaches, and long hair, but for the good of their eyes they should forget the glasses.

Normal people used to put their best foot forward by using their dress and appearances in order to make an impression. Today glasses are worn as a status symbol to make this same impression. They must do something to create an effect. With glasses on, they are the life of the party; with their glasses off, they are a flop.

I cite a case of a man who wore glasses all of his life for nearsightedness. He would never take my corrective measures, but I directed him in the second-best way, allowing his vision to tend toward normal over a period of time, as he grew older. At the age of sixty his vision was normal for distance, and because of his past history of nearsightedness, he could also read the finest print. He could do entirely without glasses, but he would not do so. I gave him plain lenses, which he still wears all the time. He

would not be caught anywhere without glasses; they were part of his person. He was glass-minded to an extreme degree.

I mentioned his case to several other men patients who consulted me, men with similar cases. They said that they could understand it. I understand also, since I know now that glasses are worn by many for more reasons than the supposed need to see. However, while I work with them and do what they ask, I dislike being a part of prescribing phony glasses for reasons other than real refractive eye trouble.

THE CASE OF THE SCHOOL PRINCIPAL AND HIS GRANDCHILDREN

Here is an example of how a principal of a grade school believed in glasses for young school children until it hit home when he changed his tune.

I was treating several young students of a grade school with corrective measures, instead of glasses. The school nurse brought it to the attention of the school principal. He stormed about it, getting in touch with the parents, telling them I was a quack, and insisted that the children must have glasses.

The parents reported it to me. I convinced the parents that the principal was wrong and unfair, and that he did not know about me and my work. That evening I mentioned it to my wife, who was a grade school teacher and also an attorney.

Unknown to me, my wife contacted the principal and tried to explain and reason with him, telling him that he was wrong and making himself liable. He defied her, saying again that I was a quack and a crook, and that sooner or later I would be caught.

Not too long after that, the school nurse reported to him that his two granddaughters had failed the school eye test and were in need of glasses. This he did not like. He did not want his own grandchildren to wear glasses, so they were brought to me. I caught them in time, and their refractive eye trouble was corrected without glasses.

In other words, the principal believed in glasses for other young children of his grade school, but not for his own two grandchildren. The principal changed his mind when it hit home.

INSTRUMENTATION EXPOSE

The most important instruments for eyemen to have when making eye examinations are the retinoscope and phoropter, and along with them a trial case plus a test chart. With them the examiner can determine the refractive and muscular eye condition.

There are other more or less novel and tricky, although less important instruments that eyemen could do without, but they are used mostly to make an impression on the patient. I could not name them all. One instrument in particular is what is known as the ophthalmometer, or keratometer. Almost every eyeman has one. There is no doubt that the use of it makes a big impression on the patient, who thinks the eyeman is looking into the depth of his eyes and his brain.

The ophthalmometer is an impressive looking instrument, large in size when compared to a retinoscope. It sits on its own stand, has a chin rest for the patient, a telescope-like tube the patient looks into from one end, and a disc with lighted mires that reflect on the cornea. It is viewed from the other end of the tube by the eyeman, who turns dials or wheels that line up the mires which are reflected on the patient's cornea. That is all. It does not look into the patient's eyes beyond the cornea, as patients would imagine.

The ophthalmometer shows no more than the conical curvature of the eyeball. If the curvature is equal in all meridians, there is no astigmatism; if it is unequal there is astigmatism. The difference in the curvatures of the cornea give the amount of astigmatism, and its axis. Astigmatism and its axis can be determined in an equally good or better way by dynamic skiametry, making the use of the ophthalmometer unnecessary. There is no need for both, unless an eyeman uses both to make an impression on the patient. Knowing the base curvature of the cornea is unimportant except in contact lens fitting, and I am opposed to contact lenses. We know that practically all corneal curvatures are around 47 diopters, more or less. Knowing this does not help in the fitting of glasses.

I have an ophthalmometer. I discarded its use forty-four years ago in favor of dynamic skiametry. I still have it, just sitting there, so that no patient can say I do not have one.

I have also discontinued the projecto chart, in favor of a plain Snellen white cardboard test chart, which is the sharpest black on white target for testing. The projecto chart letters are weaker, almost transparent black, and the white is a hazy white. It is nice to have in an office, but not the best target. Patients should have the sharpest black and white target chart possible for testing their visual acuity.

Other unnecessary instrumentation would be the amblyoscope which is made up of powerful plus lenses in the eyepiece of the tubes, having mirrors instead of prisms. The tubes are L-shaped, one for each eye, with a swivel joint between them so that they can be moved apart or together. At the other end of the tube are celluloid slides, one having a bird, the other a cage. The idea is to hold the amblyoscope to the eyes which look through the powerful plus lenses, into the mirrors, to the bird and the cage, moving the tubes together or apart to put the bird in the cage. The powerful plus lenses are sedatives to the circular ciliary muscles of farsighted eyes, which are in need of a stimulant. They would not be so bad for nearsighted eyes, but nearsighted eyes need better than that. It is a trick instrument that we could do without.

The stereoscope is a similar instrument having powerful plus lenses, combined with prisms instead of mirrors. It is held up to the face; the eyes look through the lenses to a double-picture card. The card is moved back or forth to the point where the eyes see depth, or third dimension, in the picture. The lenses affect the circular ciliary muscles about the same as that described for the amblyoscope. The prism in the

lenses affects the extrinsic muscles, which are not in need of such effect. It is another trick instrument that we could do without.

Then there is the twenty-one point technique eye examination, which had its beginning about the same time as mine some forty years ago. It was promoted to the point where it is officially recognized by our local, state, and national associations, as a standard system for eye examinations. However, not all members of the associations are followers of the system. I for one have never been a member although I have been solicited all these years. Its promoters have been given credit they do not deserve. I feel that it, and its promoters, should be thrown overboard for teaching a system that carries its followers deeper into the mire of misunderstanding. As per my book, I tell of only a few points eye examination to know the cause of the refractive and muscular eye troubles. There is no need for a twenty-one point technique.

FITTING GLASSES TO YOUNG CHILDREN BY RETINOSCOPIC TEST ALONE

One day at lunch, two men sat at a table next to mine. I could not help but hear what they were talking about. The subject was eyes and glasses. Right across from me sat a cocky little ophthalmologist. I knew who he was, but he did not know who I was. The man next to me asked the ophthalmologist, "How in the world can you fit glasses to a baby or young child who cannot read letters on a test chart?"

The ophthalmologist replied, "Oh, that's easy. We have an instrument known as the retinoscope, which throws a light into the eyes. If the eyes are not normal there will be a shadow, showing the error of refraction. Then we neutralize that shadow with lenses placed before the eyes. The lenses it takes to do that is the prescription for glasses to wear."

The other man said, "Oh, I see," as if to say that he still had his doubts, but did not know enough about the subject to say more.

Eyemen can get away with that with such young patients. They do not know whether the glasses are right or wrong. They love the novelty of the glasses, and will wear whatever prescription is given them. They even want to sleep with the glasses on. The parents think that all is well; the glasses are a perfect fit, and the eyeman did a wonderful job. The young patient's eyes grow worse from that point on.

Let the eyemen try to do that-fitting glasses from the retinoscopic findings alone-with adults, and he will find he cannot get away with it. Adults can quickly tell if their glasses are right or wrong, as glasses go. Eyemen are wise enough to know this, and the final prescription is arrived at after a subjective (chart) test. Eyemen would not dare try to fit glasses to an adult from the retinoscopic test alone, as they *do* with young patients. What eyemen cannot do with adults they cannot do for young patients.

But eyemen want it to be known that they can prescribe glasses for patients of any age. Thus all glasses for such young patients are misfitted glasses. It would be better to wear no glasses at all than misfitted

glasses, while the young patients' eyes are in the process of development. This kind of eyework needs to be exposed.

A WORD FOR ADULTS

While I am concerned mostly about the eyes of children and young people under the age of thirty-five, following are a few words about the eyes of adults.

Most adults wear bifocals. A few wear what are called reading glasses (non-bifocals). Of the two, bifocals are the safest to wear because the distance is clearer when they look up and away. Reading glasses are too blurred when they look up and away, which is not good for the eyes. Reading glass wearers will say that they remove them when they look up and away. They cannot do this fast and often enough for the good of their eyes. As a result, they will create more presbyopia for near and farsightedness for distance than they would have if bifocals had been worn.

Having bifocals does not mean that they should be worn all the time. It only means that when they do wear them they can see when they look up and away. Wearing them all the time means that when they are not doing close work, such as when walking, too often they look down through the bifocal segments, far beyond the reading distance, which is almost as bad for the eyes as reading glasses.

If one wears bifocal glasses for distance all the time, it would be wise to do something that very few will do, and that is to have a pair of glasses for distance only, without a bifocal. With these one could walk better, go up and down stairs, curbs, etc., without blurring or stumbling. Too many have had accidents just from wearing bifocals. Of course, one should also have bifocals for reading and close work, switching them when necessary. This may seem to be more or less trouble to do, but it would be safer for them and better for the eyes.

By all means, nearsighted adults should have bifocals long before the seeming need. If they are nearsighted enough, they should do their reading and close work without glasses as much as possible, even if they have bifocals, or if it seems that they have to hold their reading closer. Sooner or later they will get more range. Better yet, it would be good if they would wear their nearsighted glasses less and less for distance as they grow older, and have the lens power reduced as often as possible. In this way they might become normal over a period of time.

STIES AND CYSTS

Sties do not come from so-called eyestrain. They sometimes turn into cysts. Certainly glasses are not the remedy for them.

Sties come from a bug or germ getting into the roots of the eyelashes, setting up a pus sac. Children and

young people play with and handle dogs, cats, or other animals or birds. They rub their eyes with their unclean hands causing the sties. They could also come from colon bacillus transferred by the hand to the eyes, after carelessness at the stool or elsewhere.

Sties come and go. There may be several in succession, or at one time in one or both eyes, all from the same cause. Stop the cause, use hot packs, do not rub the eyes, and keep the hands clean thereafter. The sties will be gone in time.

BLOODSHOT EYES

Other than from infection, bloodshot eyes are often caused by physical exertion, such as stooping, bending, wrestling, lifting, running up stairs, etc., done too strenuously. Small veins in the white of the eyes are broken and seep blood, causing the bloodshot eyes. Continued exertions keep breaking the veins. Only rest and quiet will heal the veins, so that they will not be easily broken again and again, and the bloodshot eyes will clear. Bloodshot eyes could come from doing too much close work too hard, without looking up and away. They are a poor symptom for the supposed need of glasses. Those who wear glasses for bloodshot eyes will also have them with glasses, from the causes mentioned above. Eyewashes are a poor temporary remedy for bloodshot eyes from the same causes. Ordinary bloodshot eyes should not be confused with pinkeye, or other infections.

Lids swollen all the way across are usually from a cold settled in the eyes. This will be gone in a short time.

THE STUDY OF UNIMPORTANT SUBJECTS

While other eyemen spent their time thinking of other subjects, such as how to fit more glasses, details of contact lens fitting, field testing, blind spots, maculae, and other less important things pertaining to eyes and glasses, under the old traditions, I have spent my time working out a theory and method for the elimination of glasses and contact lenses for children and young people, to give them better eyes and a safer future.

As I explained, I am opposed to fitting (misfitting) glasses for wear for children and young people. I prefer to DISCIPLINE them in the use of their eyes, and watch and wait for the eyes to improve without glasses with or without corrective measures.

In contact lens work, others go into great detail as to just what the curves of the contact lenses should be, how flat or how steep, dealing in fractions of millimeters; in other words, "splitting hairs" as to specifications, etc. This is all for naught, because as with glasses, eyes cannot improve and must grow worse with contact lenses. Of the two, glasses would be safer to wear, as they do not deteriorate or degenerate the surface of the cornea or cause ulcerations, which could lead to complications. However, both have their faults.

Field testing amounts to little and accomplishes nothing, even in adult cases. Expecting eyes to detect a small target away off-center, while concentrating on a center point, is like expecting eyes to see at near, while looking at far, or seeing far while looking at near. Few people can do that. Few if any eyes have enough restricted fields to bother them in their seeing. Even if there is a more or less restricted field, little or nothing can be done about it, and they have to live with it. I have yet to find a patient who complained of, or had symptoms of a restricted field in their vision.

All eyes have their blind spot and macula. I see no good reason for even mentioning them, unless one wishes to make an impression on the patient. In refractive eye work, we should spend our time in the study of the circular ciliary muscles, dynamic skiametry, and the subjective tests. Study of the above-mentioned is secondary.

SCHOOL TESTING; DRIVERS PERMIT LICENSE TESTING

Screening of children's eyes in school is all right if done with patience and understanding. Too often a child is too timid to respond to school tests, is classed as a failure, and a note is sent to parents, who rush the child to an eyeman who invariably fits (misfits) the child with glasses. Then all is supposed to be well. The next year the child fails the eye test, this time with glasses on. A note is sent to the parents again, and a change of lenses is made, as the eyes have gone worse. This goes on and on every year or two thereafter.

The child must be able to see what is on the blackboard. So many children are going nearsighted that it would be better if the blackboard would be abolished. The nearsighted children can do close work without glasses. The glasses they get to be able to see the blackboard are twenty times wrong for close work. That is one reason why they all grow progressively worse with glasses.

What they need, if they fail in the screening eye test, is discipline in the use of the eyes and no glasses. Some teachers issue a certificate or give prizes for students who read the most books in a short period of time. This should not be done even for good eyes, unless the teachers see to it that the reading was done at a correct distance, under good incandescent light, looking up and away often. Most refractive eye troubles of children and young students can be blamed on their school work being done wrong. If they did it right, there would be few, if any, refractive eye troubles.

Therefore school eye tests, to screen out the ones showing incipient refractive eye troubles, are all right, but they should be disciplined in the use of their eyes and not urged to get glasses. The bad cases should seek an eyeman who can give corrective measures.

TEENAGE DRIVING

There is one great day that practically all boys, and most girls, look forward to from a very young age. The greatest day in their lives comes when they can drive a car.

To do that they have to pass an eye test. If they used their eyes wrong at a younger age, they cannot pass the test. Some cannot pass the test even with glasses, if the glasses are not new, they then get new glasses to pass the test, and they wear them through fear of being caught driving without them. It's "goodbye to eyes" from there on.

Let us not be so sure that wearing glasses makes for safe driving, but glasses do get them by the law. There are as many or more accidents with drivers wearing glasses than those not wearing them. However, the law calls for restrictions and glasses for driving, making it look like the law is right and I am wrong. It make no difference what condition the glasses are in-new or old, bent, dirty, scratched lenses, fit or misfit, as long as it is a pair of glasses. How can any such glasses make for safe driving?

We must know and remember that the lenses in all glasses have only one point of best vision - the optical center. Off-center, the eyes look through prisms, when looking to the right, left, up, or down and in between. Then there are the rims of the eyeglass frames that cut off vision. Outside of the rims there are no lenses. As stated, all glasses are made for twenty feet. They are wrong beyond and inside of twenty feet.

Glasses have many faults. One most important fault is that just when one has to see his best, the lenses fog up. However, with all the faults of glasses, they are worn with confidence, as if they had no faults at all. The best that can be said for glasses, as said before, is that they are a makeshift, causing more of the same trouble for which they were prescribed and are worn.

Naked eyes have faults too, but none are so bad in the beginning that one has to turn to glasses and wear them constantly, for the rest of one's life. Most of those who wear glasses had no other choice but glasses for wear. However, they could have rejected glasses and gone on as they did up to that time-without them. Instead, they accepted glasses without question. If they had only known better, as this book explains, they could have gotten along and improved their eyes without glasses. Good eyes, without glasses, make for the safest drivers, but they are subjected to the hazardous drivers who wear glasses.

EXPERIENCE WITH GLASSES

Backward, turn backward,
Oh time in your flight;
Make my eyes young again,
just for tonight.

I am weary of glasses—
I have worn them so long,
I wonder as time passes
Will my eyes— ever be strong?

Time was when I
Could read in dim light;
Now even with glasses
That light must be bright.

It seems like I'm getting
No better so fast—
And glasses to remedy,
Never seem to last.

My eyes were once perfect
As far as I knew—
Then suddenly they failed
Their duty to do.

I had them examined,
And to my surprise—
Glasses were offered
As a panacea for eyes.

Wear the glasses always,
The Doctor said to me:
The correction I have given you
Will relieve the strain, you see.

He said I would get used to them,
And in two years or so—

Come back—you'll need a change of lens;
Eyes do not stay the same, you know.

My first glasses were very mild
And simplex in their power;
I thought they were becoming,
So I wore them through every hour.

They made me so I couldn't see
Without them any more—
And before the said two years had passed
I was in the same boat as before.

A change was made thereafter—
Every one or two years as advised,
And then I began to wonder,
Would there be anything left of my eyes?

By then my lenses were much stronger
By many times of my first—
I could not reason any longer
That my eyes were not going their worst.

They're dim and they're weak,
And they're sick at their best;
Anything but strong,
Or in a state of rest.

Now if good glasses save eyes—
And it is claimed that they do.
I should not be proclaiming
My eye troubles to you.

I've tried glasses—I know,
I wish it were so—
That glasses as a remedy,
Would make eye troubles go.

I plead with you,
With my heart, my soul,
To beware of strong glasses;
Strong eyes should be your goal.

Glasses relieve one—
I'll grant you that—
They give you artificial vision,
And that is a fact.

But you'll rue the day,
You'll look back and see
What your eyes might have been,
If you had listened to me.

Glasses hurt you while they help you,
They tear down, they don't build up;
Glass help is artificial,
So glasses I would duck.

I'd fight along without them,
Forever, if you please—
If my chances I had over
I'd never seek glass ease.

Too many are wearing glasses,
They put them on too soon;
For looks, for sight, for pain and strain,
They wear them night and noon.

I've done my best to tell the rest
That of glasses I would beware;
You'll find it's true, I'm telling you
Glasses will not get you there.

How To Avoid Nearsightedness

A Scientific Study of the Eye's Behavior
by *Otis S. Brown*

December 25, 2001

Dear **I SEE**,

For the next two years I have agreed to support the publication on www.I-SEE.org of excerpts of my book, "How to Avoid Nearsightedness".

The excerpts are:

- [Contents](#)
- [Introduction](#)
- [Chapter I: Who Is Responsible?](#)
- [Chapter II: Practical Nearsightedness Avoidance](#)
- [Chapter III: The Effect of a Negative Lens on the Normal Eye](#)
- [Chapter XI: But Does it Work?](#)

The basis of this work developed from a desire to clarify and accurately portray the facts known about the behavior of the eye. So many contradictory statements were made to me about the eye that I wondered if it was possible to develop a coherent understanding of the normal eye's behavior.

I have simplified the concept of the eye's behavior in order to gain clarity of understanding. I have systematically used the term "focal state" to remove the bias that concerns misunderstandings we might develop about the fundamental behavior of the natural eye.

I believe that the objective statements made in this book about the dynamic behavior of the eye are strongly supported by direct experimental data.

This book has been prepared so that you can have the right we all should have. That is the right of choice -- to choose between two mutually exclusive techniques for dealing with a negative focal state of the fundamental eye.

If you develop your own understanding of the eye's behavior, (based on direct experimental data) and have a focal state of $-1/2$ diopter (20/30 to 20/70), you will have an excellent probability of clearing your distant vision to $+1/2$ diopter and 20/20 vision.

A Note on the Web Edition

For the web edition of this book, typos have been corrected where found. Also, Chapter XII now contains an additional letter from a woman who, after giving her daughter a more positive visual environment, watched her daughter's nearsightedness reduce by four diopters, as verified by having her daughter read the Snellen eye chart.

Ordering the Book

You may order a copy of "How to Avoid Nearsightedness" by sending a check for \$24.95 to:

The Book's Development

I developed my book, "How to Avoid Nearsightedness", subtitled "A Scientific Study of the Normal Eye's Behavior", with the expectation that would-be pilots have a right to be informed about a feasible alternative to nearsightedness. It has been extremely difficult to assemble the information contained in the book, and as a practical matter it is almost impossible to twist a person's arm to make effective use of the positive lens. The book makes clear the formidable problem one has if one mixes intellectual and experimental truth, with a public "health problem" and associated apathy. It is the health profession who deals with the consequences of public ignorance (and therefore apathy), however (and unfortunately) they tend to perpetuate the problem by failure to broach a discussion of this problem and the proper implementation of this potential solution.

Sincerely,

Otis Brown

CONTENTS

[Introduction](#)

[CHAPTER I: Who Is Responsible?](#) [1]

This section recommends that you be prepared to enter into an aggressive analytical effort if you wish to come to grips with the problem of nearsightedness. The approach must include the development of a clear understanding of the strengths and weaknesses of current eye care practices.

[CHAPTER II: Practical Nearsightedness Avoidance](#) [7]

This chapter provides a discussion of a systematic effort that you can institute to avoid myopia.

[CHAPTER III: The Effect of a Negative Lens on the Normal Eye](#) [19]

The effect that a negative lens has on the natural eye is established by scientific judgments and experiments developed over the last eighty years. The basic physics of refraction are discussed as they concern the eye.

[CHAPTER IV: A Nearsightedness Computer](#) [33]

This analysis presents an electronic computer used to portray the eye's behavior. This scientific approach reviews the data that establishes of the eye's performance when experimentally tested.

[CHAPTER V: Physiological Modeling: The Long-Term Growth of the Eye](#) [43]

Further review is provided in the form of a thought-experiment designed to simplify and clarify your understanding of eye's behavior.

[CHAPTER VI: The Response of a Dynamic Eye to a Confined Visual Environment](#) [51]

In so far as the experimental data can actually demonstrate the basic operating characteristic of the normal eye, this chapter supplies that verification.

[CHAPTER VII: A Predictive Mathematical Model for the Eye's Focal Status](#) [65]

A quantitative understanding of the eye requires the development of a basic equation for the

normal eye's behavior. The equation developed in this chapter can be solved on a personal computer, and will accurately predict the results of all possible tests that can be conducted to establish the normal eye's behavior.

CHAPTER VIII: A Conceptual Model for Tonic Accommodation [81]

This chapter reviews "dark-focus" of the eye. The normal eye, in darkness, has a slight negative focal state. (This focal state is also called blank-field accommodation.)

CHAPTER IX: The Response of a Dynamic Eye to Focal Perturbations [91]

The normal eye must continue to adjust and readjust its long-term focus. If the normal eye did not have this dynamic control characteristic (which has been experimentally demonstrated) it would be impossible to account for the fact that all eyes have a focal status that is almost identical to their visual environment, offset by +1.5 diopters.

CHAPTER X: Measuring the Eye's Focal Accuracy: A Conceptual Approach [101]

The normal eye is highly accurate (in a dynamic sense) relative to its average environment. This chapter establishes a numerical value for the tracking accuracy of the system.

[CHAPTER XI: But Does it Work?](#) [113]

A number of students and pilots, who have worked with the plus lens, detail their experience and judgment about the long-term use of the lens. Currently practiced methods, and objections to those methods are documented by eye doctors who have extensive experience with the negative lens. Books and services to assist you in returning your vision to 20/20 are also recommended.

Reprinted and expanded in 1995 and 1999.

January 3, 1999

INTRODUCTION

Dear Fellow Pilot,

This book describes the practical efforts you must make to achieve vision restoration from 20/70 (-1.0 Diopters) to normal. I am reluctant to claim that more than this is achievable. We all go through the 20/40 to 20/70 stage in the process of becoming myopic. It makes a great deal of sense to understand the critical either-or decision you must make at this point. Eye-professionals are obligated to supply you with sufficient information so that you will understand the consequences of choosing the wrong approach. Your eyes belong to you and you will be stuck with the consequences if you choose the minus-lens method. It is very difficult to reverse nearsightedness that has been made worse by a minus lens. Our responsibility is to help you and your children understand and use the proper method. Our goal is to supply the supporting rationale for prevention before the situation gets out of hand. Pages 21-23 describe the difficulties that an eye doctor might have in assisting you with this preventive approach.

Since the publication of the first edition, I have seen a friend recover from 20/320 (-4.5 diopters) of nearsightedness -- as reported in this book. You will find out the extent of your own recovery by actually implementing the preventive approach described in this book.

THE FIRST STEP: Open the book to pages 142 and 143. These pages contain the standard eye chart. Xerox the pages so you will have additional eye charts for your use. Now tape them on a wall so you can read the chart at 20 feet. If you find 20 feet too difficult, read the chart at 10 feet, and multiply the line by two. (In other words, if you read the 20/20 line at 10 feet, your vision is actually $20 \times 2 = 3D$ 40, or 20/40.) With both eyes read the lowest line possible. Write the line down with the date for future reference. You must read 4 out of 5 characters to pass the line. Now check each eye individually. If you are less than 20/100 with both eyes, recovery may be difficult. If you are at 20/40 or 20/30, recovery could be achieved in a matter of weeks. Now read the book.

The book concerns itself with scientific proof of the dynamic behavior of the eye. However, the only

proof you are interested in, is your own ability to get yourself out of nearsightedness (i.e., to change your focal state from 20/70 to 20/20). When you achieve this, you will have demonstrated the most important fact about myopia to yourself -- that prevention works when you carry out the process in a consistent, logical manner. May successful results attend your efforts!

Foreword

Ophthalmologists, optometrists and research workers are responsible for the second opinion presented in this book, that nearsightedness (myopia) is as much, if not greatly more, due to environment (and avoidable) than heredity (unavoidable).

The essence of avoiding myopia is using a plus lens (a mild magnifying glass, as in reading glasses required by older people) before the eye becomes seriously nearsighted.

If the approach advocated in this book is to work properly, you must take full responsibility to develop a clear understanding of the normal eye's behavior. In addition, you must personally implement the practical method of prevention.

In this situation we can only offer the student of science an accurate picture of existing practices, as well as an education about the fundamental behavioral characteristic of the normal eye. This approach will put you in full control of your visual welfare.

The author has demonstrated a depth of understanding of the problems and limits that occur in existing health practice. With good judgment, and personal effort, it is highly probable that you can avoid nearsightedness.

Paul E. Romano M.D., M.S.O.
Professor of Ophthalmology,
University of Florida, Gainesville

ACKNOWLEDGMENT

Over the past thirty years I have made an exhaustive effort to review the experimental data that allows us to accurately judge the eye's behavior.

In this effort I have met many fine individuals working in the diverse fields of engineering,

ophthalmology, aeronautical education, optometry, and scientific research. In addition, I have been assisted by many friends who have patiently reviewed this analysis and engaged in much discussion and review. The writing of this book was possible only with the assistance of the following individuals:

Paul Romano, MD, University of Florida
Peter Greene, PhD, Harvard University
Karel Montor, PhD, The United States Naval Academy
Dave Guyton, MD, Johns Hopkins University
Alfred Sommers, MD, Johns Hopkins Hospital
James Tielsch, MD, Johns Hopkins Hospital
Lawrence Stark, MD, PhD, Research Scientist
Vera Rollo, PhD, Author, Flight Instructor
William Ludlam, OD, Research Optometrist
Francis Young, PhD, Research Psychologist
Alan Shotwell, OD, Research Optometrist
Stirling Colgate, PhD, Research Scientist, Los Alamos
Howard Howland, PhD, Research Scientist, Cornell University
Maurice Brumer, OD, Research Optometrist
Brian Severson, Professional Pilot
Ron Berger, OD, Child Diagnostics and Treatments Associates

And last, but most important, I gratefully acknowledge Carol Brown's support. She has borne with patience the almost endless academic discussions about the normal eye's behavior that led to this book.

INTRODUCTION

It is better to light one candle than to curse the darkness. - The Christophers

It is a pleasure to produce the second edition of this book. While many scientists are convinced as to the accuracy of the facts presented in this book, we could not be certain that pilots of less experience could get the proper insight, work with the plus lens, and ultimately clear their distance vision to normal.

This book details the practical efforts that you must make in order to achieve vision restoration from 20/50 to 20/20. I cannot claim that more than this is achievable, although Dr. Stirling Colgate states that he was able to recover from 20/80. You will find out the extent of your own recovery by actually implementing the preventative procedure described in this book.

IS THIS BOOK FOR YOU?

This book is designed for use by two groups of individuals; the research scientist who is willing to develop a thorough understanding of the fundamental behavior characteristic of the normal eye, and the person, for example a would-be pilot, entering a four-year academic institution, who wishes to be visually qualified upon graduation. It is also of interest to parents of school-age children.

It is possible to avoid nearsightedness. Recovery from nearsightedness has been successfully accomplished, for example by Stirling Colgate, a scientist who developed a clear understanding of the normal eye's behavior. It is, however, almost impossible to recover from anything more than a slight amount of nearsightedness. Because of the difficulties of recovery, it is important that you clearly understand the scientific basis for this alternative approach.

This alternative has been developed over the past three decades by the eye care profession and is currently practiced by twenty percent of the profession. The practice requires the use of a plus-lens (bifocal) for children who are slightly nearsighted. This development (of the second-opinion) encourages us to look more deeply into scientific experiments that resolve the normal eye's behavior.

THE FIRST STEP

Open the book to last several pages. These pages contain a standard eye chart. Xerox the pages so you have additional eye charts for your use. Now tape them on a wall so you can read the chart at 20 feet. With both eyes read the lowest line possible. Write the value down. You must read 4 out of 5 characters to "pass" the line. Now check each eye individually. If you are less than 20/70 with both eyes, recovery will be difficult. If you are at 20/30 or 20/40, recovery could be achieved in a matter of weeks.

SEQUENCE OF PRESENTATION

This book explores three major scientific subjects:

1. What practical steps must you take to avoid nearsightedness? (Chapter One to Three) Is the method effective? (Chapter Eleven)
2. How does the natural eye behave when it is actually tested? (Chapters Four to Seven)
3. Why must the natural eye function as a dynamic system, rather than as a passive system? (Chapters Eight to Ten)

This book will help you understand how the eye behaves under direct experimental control. After you understand this behavior, you can then begin to devise a strategy to successfully avoid nearsightedness.

EXPERIMENTAL VERIFICATION OF THE EYE'S BEHAVIOR

This book is based on directly-obtained experimental data. The facts clearly define the behavior characteristics of all natural eyes.

When the eye is placed in a confined visual environment, or wears a negative lens, (such as is currently being prescribed for nearsightedness) the normal eye will change its focal state in a negative direction. When the normal eye is placed in an open environment, or wears a plus lens, the focal state of the eye will change in a positive direction -- thus achieving successful myopia avoidance. Both theoretical analysis and direct experimental testing has confirmed this fundamental behavior characteristic of the natural eye. (The plus and minus lenses will be thoroughly discussed later in this book.)

The concept of the eye's behavior presented in this book is technical in nature. However, I feel that most readers will be able to understand most of the analysis. A detailed understanding requires an engineering background. If you develop this insight, you will be able understand the nature of the normal eye's behavior. The student of science will eventually be able to do this. For this reason I have not excessively simplified the scientific presentation.

If you will make the appropriate effort to understand the eye's behavior, you will eventually be rewarded by your own successful effort to defeat nearsightedness.

A SCIENTIFIC APPROACH

The outlook of this book follows the English (Scientific) Royal Society's Motto, "Nullus in Verba", which has been best translated as, "Take nobody's word for it; see for yourself." The first step in learning to make a scientific judgment is to learn to make your own decisions, based on your own measurements.

Your eyes belong to you, and you must control your own visual future. The only way to make a responsible decision is by being cognizant of your focal state. With this knowledge you can act effectively to control the behavior of your eyes.

THE EYE CHART

A standard eye chart is included in the back of the book. You should use this chart to confirm your current focal status. A reading of 20/60 or 20/70 is not disastrous. You should, however, take this situation as a warning and consider the alternative. Even if you read the chart at 20/20, there is no guarantee that after four years of study and close work you will graduate with 20/20. At the United States Naval Academy approximately 30 percent of the entering class are disqualified from flying due to failure to read the 20/20 line upon graduation!

THE EXPLICIT RECOMMENDATIONS OF THE EYE PROFESSION

Because ophthalmologists are aware of existing experimental studies, they have strongly suggested that prevention is the best solution for the problem of nearsightedness. Unfortunately, this recommendation has never been effectively presented and acted upon. Although the correct solution is known, the

methodology of prevention has never been implemented.

There is direct testimony as to the effectiveness of the use of a positive (plus) lens to control the negative focal state of the natural eye. Many children and adults can help themselves if the principles in this book are properly understood and applied.

A PERSONAL NOTE BY DR. STIRLING COLGATE

Dr. Stirling Colgate, a research scientist with the Los Alamos National Laboratory, correctly deduced the behavior of the normal eye, and began using a plus 2.5 diopter lens to reverse the effect of a confined environment on his eyes. By doing this, he successfully recovered from a slight amount of myopia.

"Fortunately, I understood most of this for myself when I was studying biology and physics when I was 14. I first started to become nearsighted at 13 to 14. As soon as I noticed it, I immediately acted upon it by buying a pair of reading (farsightedness) glasses, (positive lenses), at the dime store. I used these for reading. A positive lens substitutes for further contraction of the ciliary muscle; thereby allowing the eye focus to remain in the relaxed state of infinity when reading a book up close. Within several weeks my eyesight had returned to normal -- relaxed state of focus at infinity."

"Since I am a physicist I am not dependent upon optometry or ophthalmology for my professional peer group. I have managed my own eyesight all during my life (now 63). I have undertaken to try to explain this because I believe that the condition of myopia (and then having to wear nearsighted glasses for life) is totally unnecessary for the majority of the human race. I believe that the condition of progressive myopia is a grotesque and needless distortion of human physiology, created by our intellectual environment of reading and continued because of our collective denial of that very intellect."

CONCLUSION

If a fourteen-year-old can figure out how to act effectively to avoid myopia then you should be able to duplicate his successful preventive effort.

This book contains a detailed scientific and engineering assessment of the normal eye's behavior. If you wish to develop a complete understanding of eye's behavior under testable conditions, then review Chapters Four through Ten. The previous discussions about problems of the eye have been qualitative. A qualitative statement is very difficult to test in a scientific sense, and often has imbedded bias and assumptions. These arguments (about the cause of the defective eye) have not led to a clear understanding of the normal eye's behavior. To encompass a full and accurate understanding of the eye it is necessary to develop a precise quantitative model of the eye's behavior.

It is always difficult to develop a book that advocates change in existing medical practices. However, if we are ever to come to grips with a major scientific problem, we must be willing to generate criticism of

existing practices so that at least a few of us will have the opportunity to effectively defeat the problem of nearsightedness.

This book applies only to nearsightedness that is preventable. You should consult with an ophthalmologist or optometrist if you think that the blur at a distance is a result of a diseased condition such as detached retina, glaucoma, etc. After you are assured your problem has to do only with the refractive state of your eyes, you should proceed with the preventive approach recommended in this book.

How To Avoid Nearsightedness

Reprinted and expanded in 1995 and 1999.

Chapter I: Who is Responsible?

We have met the enemy and they is us. - Walt Kelly

INTRODUCTION

It is difficult for us to change our habits of thought and practice, even when they lead to unhappy consequences. Very few of us will accept an uncommon proposal if that proposal involves the use of a preventive lens on the (almost) normal eye.

LEARNING TO TAKE MAJOR RESPONSIBILITY FOR YOUR OWN WELFARE

You must eventually decide how worthwhile maintaining normal 20/20 vision (focal state 0.0 to +1.5 diopters) is to you. If a plus lens is thrust upon you and you do not understand the reasons why you must use the lens, it is unlikely that you will persist in the effort long enough to achieve the desired result.

Only you can know how much effort you have actually put into your plus lens use. It is you who must verify that your eyes were 20/40 when you started using the lens and that your eyes have changed in value from 20/40 to 20/20 after several months of intensive plus lens use.

HOW DO WE ACCURATELY REPRESENT THE NORMAL EYE'S BEHAVIOR?

Up to the 1960's there was no high quality experimental data available by which one could judge the normal eye's behavior. For the last 25 years, increasingly better quality experimental data has been presented which does establish the fundamental behavior characteristic of the eye. To my knowledge, this information has never been made clearly and consistently available to the layman who has a

compelling desire to avoid myopia. Such a person, with proper assistance, is most likely to make effective use of the recommended approach described in this book.

The analysis in the book concerns only nearsightedness that results from the fundamental behavioral characteristic of the normal eye. Since most nearsightedness is of this type, major emphasis is placed on the study and resolution of the normal eye's behavior.

PREVENTION IS DIFFICULT

We should learn from the man who successfully defeated the myopia situation. Dr. Stirling Colgate details his struggle and success with the problem in the following paragraphs.

"Science has progressed to understanding this mechanism of slow adaptation of the relaxed focal length (focal state) of the eye to its average focal environment. A significant number (several dozen) professional people in ophthalmology and related disciplines have empirically and intuitively come to the same conclusions (that nearsightedness is preventable) and unsuccessfully attempted, even with the dedication of a lifetime, to reverse the orthodox view of solely genetically determined eye focus."

"Many individuals in the ophthalmology profession have not yet recognized a mechanism of slow adaptation of the relaxed focal length (focal state) of the eye to its mean focal environment for various reasons. Among these reasons are:"

1. "There is a long-standing orthodox view that all focal states are hereditary and therefore nothing affects focus after conception."
2. "The public demands instantaneous sharp vision; i.e. Johnny can't read the black board and I won't stand for any nonsense about getting glasses that make it still fuzzier -- even temporarily."
3. "The scientific understanding of the (normal) eye's development is not yet widely published, so there is always an excuse to ignore it."
4. "There have been many non-scientific books about sight-without-glasses that have not logically argued the reasons, not given the physics background, nor have they discussed the biological mechanism. For example, eye exercises involve contracting the ciliary muscle, causing a nearer more myopic focus and, therefore, resulting in a negative change of focus for the eye."
5. "If reading glasses were used at the onset of myopia, up to 90 percent of nearsightedness could be avoided. Furthermore, reading glasses should cost no more than \$5.00 to \$7.00 to manufacture and sell for \$10.00 to \$15.00 without a prescription."
6. "Many optometrists and even some ophthalmologists believe that myopia and wearing glasses is not such a bad thing; after all, many people want to buy glasses in order to look chic. The very many that undergo the discomfort and expense of wearing contact lenses is an overwhelming vote to the contrary. People would rather not be nearsighted."
7. "Finally, social pressure of intellectual achievement is forcing the age of first reading to an earlier, even preschool age, hence causing earlier myopia, and a potential for further progression."

WHY DO SO FEW PEOPLE KNOW ABOUT THIS?

"It is perhaps worth speculating why there has not been any prior recognition by the medical and optometry professions of the approach to the management of eyesight focus. I believe there are many additional 'reasons' but I have heard these:"

1. "Nearsightedness is not a very severe handicap, and mostly those affected are studious anyhow and don't need distance vision."
2. "It is not a problem for medicine and so medical doctors are not concerned."
3. "If you don't want to be nearsighted, give up reading."
4. "Negative lenses that correct nearsightedness are relatively cheap and easy to wear so why bother with another approach."
5. "Glasses are a status symbol of the intellectual."
6. "Contact lenses make nearsightedness even less of a problem."
7. "Only recently has nearsightedness become a severe problem -- it is both more prevalent and, because of earlier onset, leads to progressive myopia."
8. "Traditionally, medicine treats or cures the symptom and, only recently, is preventative medicine respected."
9. "Only very recently is there a rational scientific explanation for the scientific observation of the developmental mechanism of the normal eye."

"Only the last statement is acceptable to me. So now that there is such a scientific basis, let's get on with the solution."

HOW DR. COLGATE DEFEATED THE PROBLEM

"Now I assume that you are young, 8 to 20 years old; have recently (within months) started or gone nearsighted and don't want to go on with thicker and thicker negative lenses for distant vision. You buy and wear positive lens reading glasses for all your reading -- or anything up close, and even for some of the rest of the time. You might get a bit of a headache at first; if so, decide which comes first -- the headache or myopia, and adjust the use of the positive lenses accordingly. Monitor your own mean relaxed focus, i.e., distance vision at least once a day.

"I may or may not be average but it took me only 2 weeks when I was 14 years old to return my initial myopia (about 20/80) to normal vision, i.e., (20/20) eyesight. (20/20 vision means that you can see at 20 feet what a "normal" person sees at 20 feet.) Twenty feet is almost the same as infinity; (20/80) vision is the start of myopia. I could see at 20 feet what good eyes could see at 80 feet. I was studious, slightly shy, introverted type -- which also included, fortunately for me, a course in physics at that age. That is when I first understood the simple facts about lenses and optics and the absurdity of using a negative lens when I was becoming nearsighted.

"I bought my own reading glasses in the dime store. They were plus 2.5 diopters and stronger than I needed, but they did the trick in a hurry. If you catch the start of myopia before the lens muscle spasm leads to irreversible lengthening of the eyeball (change of focal state), then it seems that the eyesight returns to 'normal' rapidly.

"If you make up your mind what value the mean relaxed focal distance you want in life, you can manage or lead your eye to that condition. When several times I lost my reading glasses during the war (World War II), I could not get them replaced by military optometrists because my glasses were not orthodox. I rapidly became myopic again; at 17 I read a lot in the Merchant Marine. I restored my vision to 20/20 as soon as I could purchase positive lens reading glasses when I returned to the States.

"During the war there was much social pressure to get into the officers' college training programs, but 20/20 was required. A few optometrists recognized the need and they prescribed positive lens glasses for myopic young people who desperately wanted to get into the Navy V-12 training program. This technique worked for many who were moderately myopic. An optometrist at Cornell was surprised that I had been doing this successfully since the age of 14.

WHAT WE SHOULD LEARN FROM DR. COLGATE

1. Nearsightedness prevention is possible -- if the work is done properly.
2. You must have the internal competence and desire to do the job logically and consistently, and must have a compelling personal reason to want to succeed.
3. The effort must be conducted as soon as the situation is detected (20/40, -1/2 diopter myopia)
4. You must take the time to learn and understand the behavior of the normal eye.

How To Avoid Nearsightedness

Chapter II: PRACTICAL NEARSIGHTEDNESS AVOIDANCE

The formulation of a problem is often far more essential than its solution, which may be a matter of mathematical or experimental skill. To raise new questions, new possibilities, to regard old problems from a new angle, requires creative imagination and marks real advances in science. - Albert Einstein

You cannot cheat nature, however much you may cheat your fellow man. - Galileo

THE FACTS ABOUT THE EYE'S BEHAVIOR

Your understanding of the facts that establish the natural eye's behavior will eventually determine your success in avoiding myopia.

There are two categories of facts that must concern you. If I tell you that there are more than one million stars in the universe, you might believe me. If I tell you that the paint on a bench is wet, you will reach out and touch the bench. The facts that I present must be as clear and convincing to you as wet paint on a bench.

The facts presented in this book can always be confirmed by yourself in the same manner that you would confirm that a park bench has wet paint. If you ran your own experiments you would find that the normal eye can be driven towards nearsightedness by either a negative lens or a confined environment. Understanding this fact is crucial to understanding the normal eye's behavior.

The next step is to recognize that your eyes behave the way that all normal eyes behave. By substantially changing your near environment into a "far" environment you can successfully recover from a slight amount of myopia. This requires that you have a logical, self-disciplined mind that will go from fact recognition, to a process of implementing a solution that meets your personal needs.

THE HISTORY OF EXISTING PRACTICE

The use of a lens to deal with any and all problems of the eye began in the 14th century. The practice of using a negative lens for nearsightedness has continued, almost unchanged, for the last 300 years. The compelling reason for this practice is the public's demand for an instant solution, and a corresponding refusal to consider the use of an alternative approach.

A REVIEW OF THE PAST APPROACH

We should all thoughtfully evaluate the unfortunate effect of using an immediate and easy fix for the problem of nearsightedness. This situation of a self-perpetuating mistake (produced by public need and attitude) is sometimes recognized by the students of medicine. Dr. Perri Klass said it this way in VITAL SIGNS:

"... Sometimes the awesome weight of medical knowledge is totally off the beam. You have to practice medicine with that in mind, with the knowledge that a hundred years or so along the road, they'll be telling stories about the medical theories of today to get a laugh of the medical students of 2085..."

And about medicines' confidence in its routines:

"... Or something so basic, so taken for granted, that no one has gotten around to questioning it. Whatever it is, probably the medical profession is collectively doing something really dumb and really damaging, and doing it with complete good will and typical medical self-confidence."

This applies to vision. The demand for negative lens use comes partly from the public's demand for an instant solution, (and corresponding reluctance to properly use a plus lens) and not from a scientific assessment of the behavior characteristic of the normal eye.

HOW DOES THE NORMAL EYE BEHAVE WHEN IT IS ACTUALLY TESTED?

Much of this book concerns testing and verification of the natural eye's behavior. This work, although absolutely essential, cannot give you immediate guidance in your effort to get yourself out of a slight amount of nearsightedness. You should, however, read on in order to understand the following optical principles.

WHAT IS A POSITIVE LENS?

The positive lens, when properly used, will change a near environment into a "far" environment. This is the desired objective.

THE PLUS LENS MAKES DIVERGING RAYS OF LIGHT PARALLEL THUS KEEPING THE NATURAL EYE IN AN "OPEN" ENVIRONMENT

Subjectively, the lens (which is a low-power magnifying glass) makes the object look slightly larger. People have reported that the lens reduces eye-strain caused by close work. The lens has been used for over a century for this purpose, and it is recommended and used by the eye-care profession. The plus lens is regarded as absolutely safe for all reading.

Such a lens must have a strength of greater than +1.5 diopters if the glasses are to achieve the desired result in a reasonable period of time.

WHERE CAN I PURCHASE POSITIVE LENSES?

Because a positive lens is not a prescription lens, the glasses are sold in almost all pharmacies. They sell for about \$10 to \$12, and are rated in terms of diopters and/or focal length. A 2.0 diopter lens would be used at 20 inches, and has a focal length of 20 inches. If you habitually read at 25 inches then you would use a 1.75 diopter lens. The power of the lens is normally stamped on the bow of the glasses.

If you wish to determine the focal length (power) of the glasses by direct measurement, hold them up in sunlight above a flat surface. Move the lenses up and down. Find the distance where the sun forms the sharpest and smallest image. Then measure the distance from lens to surface. The focal length is the reciprocal of lens power:

Distance In Inches	Focal Power
40 Inches	1 Diopter (Weakest)
20 Inches	2 Diopters
13 Inches	3 Diopters
10 Inches	4 Diopters (Strongest)

HOW DO I USE THE POSITIVE LENS?

Once you select the lens that you feel is best for you, (between 1.5 to 2.5 diopters) select some reading material. For a starting point, hold the reading material about twelve inches from your eyes. Gradually move the print away from your eyes and note the point where the print just blurs. This point should be your habitual reading distance. If you habitually read closer, you will need a stronger lens. If you read at a greater distance you need a weaker lens. Some experimentation is in order here, and you may try

several pairs of glasses before you find the right pair for yourself. In general, stronger is better, but you will want to be comfortable with the lens you choose.

If you have never used lenses before, you will notice a slight disorientation when you read close (with the lenses on) and then look in the distance over the tops of the lenses. This is a good indication that the lenses are having their desired effect. The reason for this is that the lenses have placed the near work at a distance while the convergence system believes the work is close by. This situation is normal and is part of the price one must pay to avoid nearsightedness.

UNDERSTANDING THE EYE CHART

This chart is called the Snellen eye chart. In daylight, the normal human eye can resolve objects that are separated by about one inch at 100 yards. This is 1 minute of angle resolution. The typical eye chart displays letters that cover 5 minutes of angle. To read the letters on the chart requires the ability to separate the white space from the black space. This is the most common method of quickly determining the resolving power of the eye. Over the past 100 years, the standard distance for this measurement was set at 20 feet with normal room illumination. The letter size for 20 feet is 3/8 inch. The letter size for 20/40 vision is therefore 6/8 inch, and so forth.

HOW TO READ THE EYE CHART

Reading the eye chart is straight-forward. Place the chart at 20 feet and start reading from the bottom up. You will find variability in your readings. Some days you will be able to read the 20/20 line without difficulty. Other readings will drop to 20/40 or 20/60. As the plus lens begins to have the desired effect, you will find that you can more consistently read the 20/20 line.

THE FAA REQUIREMENT

We can use the Federal Aviation Administration's considerable experience in testing eyesight. The requirement for the First Class Medical Certificate (Airline pilot requirement) for flying, is the ability to read four out of five characters on the 20/20 line. You should check and double check your visual state by yourself so that you understand and trust the measurement. Use the FAA method of measurement as the standard. This measurement is made in a well-lighted room, with the eye chart at a distance of twenty feet. I recommend that you set up the eye chart (in the back of the book) and check your eyes as soon as possible.

THE FAA CLASS MEDICAL VISUAL REQUIREMENTS

3rd CLASS:

Distant vision -- at least 20/50, without correction; or if vision is poorer than 20/50, must correct to 20/30 or better with corrective lenses.

2nd CLASS:

Distant vision -- same as 1st.

1st CLASS:

Distant Vision -- 20/20 in each eye separately without correction or at least 20/100 in each eye separately corrected to 20/20 or better with corrective lenses.

WHAT MUST I DO IF I CANNOT READ THE 20/20 LINE?

In checking your focal status, you will determine either that you can or cannot read the 20/20 line. If you read the 20/40 line you will still pass the state test for a driver's license. (The 20/40 line translates into a focal state of about -1/2 diopter.) If as a potential military pilot you cannot read the 20/20 line your professional flying career will go on hold.

The Naval and Air Force Academy students (who are not offered the use of the plus lens) never recover from a slight amount of nearsightedness. It is also true that the Naval and Air Force Academy will not accept you for a flying career if you have less than naked eye 20/20. However, the Air Academy has recently relaxed its requirement, and will allow you to continue with less than 20/20.

The airlines have changed their policies -- somewhat. Delta categorically requires naked eye 20/20, but the other airlines have changed their requirements from a minimum of no worse than 20/30 (focal state - 0.25 Diopters), to a minimum of 20/100. If you use a "quick fix", or negative lens, your vision will worsen, and there is a high probability that you will go below the Airline minimums, even with a waiver. It is a situation that you should wish to avoid.

The experimental data, and the testimony of scientists and ophthalmologists, indicates that you can recover from 20/60. It is obviously better to get out of nearsightedness. Given the choice between a nearsighted pilot and a non- nearsighted pilot, the airline will choose the pilot who can read the 20/20 line.

The approach recommended in this book requires that you wear the plus lens for almost all close work, and take over complete control of the situation. This requirement may perhaps seem a burden, but you must decide -- the inconvenience of plus lens use, or the loss of your career as a professional pilot with the loss of your distance visual acuity.

If your vision is 20/60, you should persistently wear your lenses and check your eyes once a week. You can personally determine when you can again read the 20/20 line. It may take from three to six months to

again read the 20/20 line. Once you can read the 20/20 line you should continue using the plus lens for another two or three months. You should continue checking your eyes at monthly intervals -- just to make sure that you will be able to pass the FAA exam when you are required to do so.

If your myopia returns (after not using the plus lens for a while) you will have to start the process again. It is best if you control this entire process yourself.

OTHER CURRENTLY PRACTICED METHODS

While I strongly recommend that you use the simplest and least expensive approach (less than \$100) to avoiding (and recovering from) nearsightedness, for sake of completeness I will discuss two other existing practices that will produce recovery.

RADIAL KERATOTOMY (CORNEA CUTTING)

This approach involves the physical cutting of the cornea (the transparent surface of the eye). The approach produces uncertain results, and costs approximately \$ 3,000 per eye. The Air Force will reject you if you have this done, even if you obtain 20/20 vision.

ORTHOKERATOLOGY (ORTHO-K) (CORNEA RESHAPING)

In orthokeratology, a hard contact lens of larger radius than the cornea (see page 20) is used. This lens is force-fit onto the eye, thus changing the shape of the cornea. This approach costs from \$1,000 to \$2,000, and will produce vision restoration if your vision is on the order of 20/80.

AM I SAFE IF I CAN READ THE 20/20 LINE?

Even if you read the 20/20 line when you enter a four-year college there is a good probability that you will fail the eye chart before graduation. You should monitor your eyes by placing the eye chart in your room and occasionally verifying that you can easily read the 20/20 line. When a day arrives that you cannot clearly see the 20/20 line you should initiate the plus lens procedure. It is better to know about this method beforehand so you will not panic when you get into the situation.

WHAT IS THE PROBABILITY THAT I WILL BE NEARSIGHTED ON GRADUATION?

For the past 50 years, the U. S. military academies have been monitoring the focal behavior of the normal eye. They have determined that the average eye goes downhill at the rate of about -1/4 diopter per year.

If one has a focal state of zero diopters on entry, one has about a 10 percent chance of graduating with 20/20 vision. If the focal state is +1.0 diopters one has about a 90 percent probably of graduating with 20/20 vision, although the focal status will have changed from +1.0 diopters to 0.0 diopters over the four years.

MEASUREMENTS

You could check your own focal state if you had the proper set of positive lenses to do so. Failing this, you should find a cooperating optometrist or ophthalmologist who will check you focal status. Make a note of this measurement. If the value is + 1.0 diopter for each eye you will almost certainly graduate with 20/20 vision. If the value is 0.0 diopters, you can be almost certain that without intervention you will sink below the 20/20 line during your four years of intensive work.

A number of eye-measurement approaches are used by the eye profession. Some eye Doctors will use a small "box" with an eye chart which you look into. Others will have you read an eye chart in a darkened room. These different methods of measurement will produce different and inconsistent readings. If you are told you have 20/40 vision in a darkened room, you may find that you have 20/20 in a well lighted room.

If you find that you can read 20/20 line, and you have recently received negative lenses for nearsightedness, you should find an FAA medical examiner, make an appointment, read the eye chart for him, and get the "must wear negative lenses" requirement removed from your FAA license. You should, in addition, still use the approach described in this book to insure that you never again get back into nearsightedness!

ADVICE FROM OTHER SOURCES

You will undoubtedly get advice from many sources. Much of this advice will be confusing and contradictory. Each group has its own vested interest. The health profession must cater to everyone, and its procedure must work instantly on everyone. Health professionals cannot easily sort out who will take the initiative to make the preventative effort work successfully. Some have (privately) recommended the approach suggested in this book.

THE SCIENTIFIC COMMUNITY

For at least twenty years scientists have recognized the reason and the need for plus-lens use to prevent the occurrence of nearsightedness.

It is impossible to impose prevention or conduct a preventative study until each individual is aware of the history of the problem as well as the nature of the probable solution.

THE MEDICAL COMMUNITY

For the past twenty years the medical and health community has consistently advocated prevention with the plus lens.

Faced with a public misconception about the use of lenses for the eye, the doctor (who must deal with the public) is forced to follow the tradition of the last 300 years -- regardless of the long-term consequences. The health profession has recognized that the situation requires a strong personal preventative effort but is unable to persuade most individuals to consider and use the alternative approach.

CONSEQUENCES OF FACT RECOGNITION

The consequence of a careful review of the experimental data that clearly establishes the behavioral characteristic of the normal eye causes us to reject the idea that a positive or negative focal state of the eye represents any defect of the eye. The normal eye always controls its long-term focus. The use of a negative lens when you are on the threshold of the situation virtually guarantees that your nearsightedness will worsen and become non-recoverable.

The only way you personally can be certain that you understand the normal eye's behavior is to perform the critical experiments yourself. If we desire almost absolute proof that the normal eye is a dynamic system, then we must develop a mathematical concept of the eye's behavior and rigorously test that concept.

SUMMARY

This book concerns itself with two distinct and separate problems.

1. Factual and intellectual work, now completed, which verifies the fundamental behavior characteristic of all normal eyes.
2. The requirement of the scientific profession to inform the would-be = pilot about a reasonable approach to defeat nearsightedness.

Care for the defective eye is a responsibility that is thrust upon the health profession. The responsibility for dealing with and judging the normal eye's performance is a scientific responsibility. These two responsibilities are often confused.

In the past would-be pilots have become nearsighted with no intimation of a solution. Nor has any warning been explicitly provided to these young men about the inherent danger of negative lens use. The tragedy is not that nearsightedness develops with predictable and monotonous regularity but rather, that

the would-be pilot (who would desperately like to get out of the situation) is not adequately warned and offered a practical alternative.

How To Avoid Nearsightedness

THE EFFECT OF A NEGATIVE LENS ON THE NORMAL EYE

Truth is so obscure in these times,
and falsehood so established,
That unless we love the truth
we cannot know it. - Blaise Pascal

THE HISTORICAL OPINION OF THE USE OF A NEGATIVE AND POSITIVE LENS FOR NEARSIGHTEDNESS

Over the past eighty years, eye doctors have become increasingly suspicious of negative-lens use for nearsightedness. While the immediate effect is instant clarity of vision, the long-term effect has been recognized to be bad. For instance Dr. Samuel Drucker said: [\(3\)](#)

The suspicion began to dawn on me slowly that among the causes of progressive myopia it might be necessary to list concave lenses themselves. From many articles that have appeared in the past on the subject of 'Optical Poison', a familiar term a decade (1930) ago, many other optometrists appear to have the same idea.

An optometrist in Ontario (1938) says that, "...he would like to have a law established and enforced that would make it a misdemeanor for any refractionist (optometrist) to prescribe minus glasses for any child unless under very extenuating circumstances." [\(3\)](#)

These are strong opinions by individuals who have had direct and prolonged experience with the use of a negative lens and the effect that this lens has on the normal eye.

Doctors, some time ago, have correctly deduced the nature of the problem and suggested the correct solution. For example, Chalmers Prentice, wrote the following in 1895: [\(3\)](#)

In the nomad, who is reared out of doors, and who follows such pursuits that his vision is mostly used at twenty feet and greater distances, the nerve-impulses to the ciliary (lens) muscle become established so that the easiest vision is for the far point, and in many years of such use, these impulses become more or less fixed; while the child of a higher civilization spends his life within doors, amuses himself with toys, picture books, kindergarten amusements and learning to read.

We will assume that such a child generally holds his book or toy 10 inches (4 diopters) from his eyes, in which case the crystalline lens requires a much greater convexity, or higher state of refraction to bring about perfect vision; and this is brought about by an increase in the ciliary nerve-impulse which changes the shape of the ciliary lens. Through long continued use, this impulse becomes comparatively fixed, and in some instances refuses to suspend itself sufficiently to bring about distant vision again, and so myopia has set in. The regular work of the student and those other pursuits which require the use of the eye at the near point, tend to perpetuate this condition and make it progressive.

...Again, the important question, 'How are the advantages of a high civilization to be attained without the foregoing disadvantages?' If the eyes are to be used at a distance of ten inches, aid them artificially by a ten inch magnifying glass; then the nerve-impulses to the ciliary muscle will be no more than if the patient were leading an outdoor life and viewing objects at twenty feet or more.

It is clear that the collective common sense of the profession has indicated the type of problem they face and the nature of the expected solution. In the article "Trying to Get Myopia into Focus", (1987) Dr. Theodore Grosvenor of the Houston College of Optometry, insists that persistent close work causes myopia. He also states that; "Once the eye has started to stretch, it may be too late to keep it from stretching. The ultimate study would be to put reading glasses on first-graders, before anyone has developed myopia." [\(4\)](#)

WHY ISN'T THE PREVENTATIVE APPROACH OFFERED?

With this type of scientific understanding of the eye's behavior, you would think that the insightful and motivated optometrist or ophthalmologist could introduce a practical and effective method of solution. Dr. Jacob Raphaelson did exactly that in the following example -- with the following result:

THE PRINTER'S SON

"It was the year 1904 that I met a mother at a social lodge meeting. She told me about her son's trouble with his eyes in school. I gave her my card and told her to bring him to my office and I would fit him with a pair of spectacles.

"She said that she had no money at the time and that her husband was a printer working in another city. She did not expect him home for the next six weeks. I told her all this would not matter, that she should bring the boy over and I would fit him with a pair of spectacles. I told her that she could pay for them when her husband returned home.

"She brought the boy in and I examined his eyes. I found that his vision for distance was poor. It was less than 20/40. I made him a pair of plus 1.00 diopter spectacles. She was to pay me when her husband came back home.

"In about six weeks she came back and returned the glasses to me. She stated that her husband was provoked with her for getting the glasses. He had tried the boy's eyes with different prints, far and near, and had found him to have perfect vision with his naked eyes. In fact, she said, the boy could see even better without the glasses than with them.

"I was surprised that the plus lens could produce recovery that quickly. I could hardly believe this story. I persuaded the mother to bring the boy back to let me check to see if he could really see well with his naked eyes. She again brought the boy in and I checked his vision. I found that the father was indeed right. The boy had good eyes, with 20/20 vision and better.

"I was in a dilemma. I did not have the nerve to say anything to the mother. I just let her go. How was I to prove that the boy had poor vision before he received his glasses? And who would believe that vision could be restored by just wearing a pair of plus 1.00 glasses for a few weeks?

"My experience with the printer's son aroused my inborn tendency for exploration. It gave me an incentive to try to do special work on children's eyes and on vision restoration. It also enticed me to investigate myopic (nearsighted) eyes because I was myself nearsighted.

"On the other hand, this experience was a warning to be cautious in doing such work. For selling spectacles to persons who, supposedly, did not need them was almost a crime. And the fitting of glasses without the advice or consent of a medical doctor to unhealthy or diseased eyes, or even to an unhealthy person who might need or be under medical attention, was, and is now, and encroachment on the medical profession.

"To shield myself against possible enmity and involvement, I took the following precautions: First, I quit using the title 'doctor' in any form, in print or verbally. I was to be known as a spectacle fitter and nothing more. Second, I charged a reasonable price for the spectacles I sold but nothing extra for any special work or relief I gave. I did not advertise about this special work. I just did it as a matter of routine whenever or wherever I was given the opportunity.

"Thus in 1904 I became an independent researcher on the relationship of the eye's behavior to spectacles, vision, and health. I have kept it up, and will continue to do this work as long as I continue to have the incentive and capability.

"Who would believe it? Who would believe that by just wearing a pair of plus one (+1.00) glasses for a few weeks, that normal vision to the naked eye could be restored to children whose eyes have a negative focal state? This was true in 1904, and it is also true now, in this decade of 1950." (It continues to be true in this decade of 1990 -- Otis Brown)

SCIENTIFIC VERIFICATION

With such strong recognition that a negative lens has such a profound and adverse effect, you would think that it should be possible to develop scientific verification for this characteristic of the normal eye. You would be correct. The testing and verification is impeccable -- if we restrict our attention to the normal eye's behavior.

BASIC OPTICAL PHYSICS

In order to understand the design and behavior of the normal eye it is necessary to understand its basic optical properties.

When a light ray enters water it is refracted (bent). The equation that describes this bending is shown below. Water has an Index-of-Refraction of 1.33. The normal eye has 1.38 as an over-all Index-of-Refraction. (Figure 1)

SNELL'S LAW OF REFRACTION

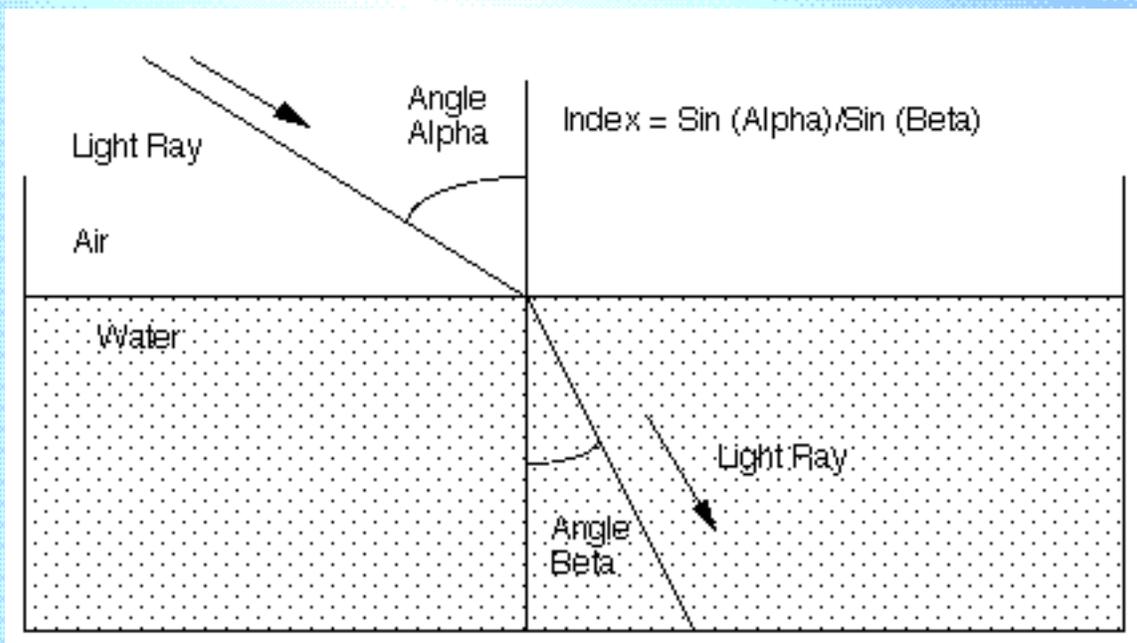

Figure 1.

When light travels through a curved surface, the light rays converge on a single point. Since an image is made up of a large number of points of light, an image will form where the light rays converge. (Figure 2)

THE APPROXIMATE REFRACTIVE CHARACTERISTIC OF THE EYE

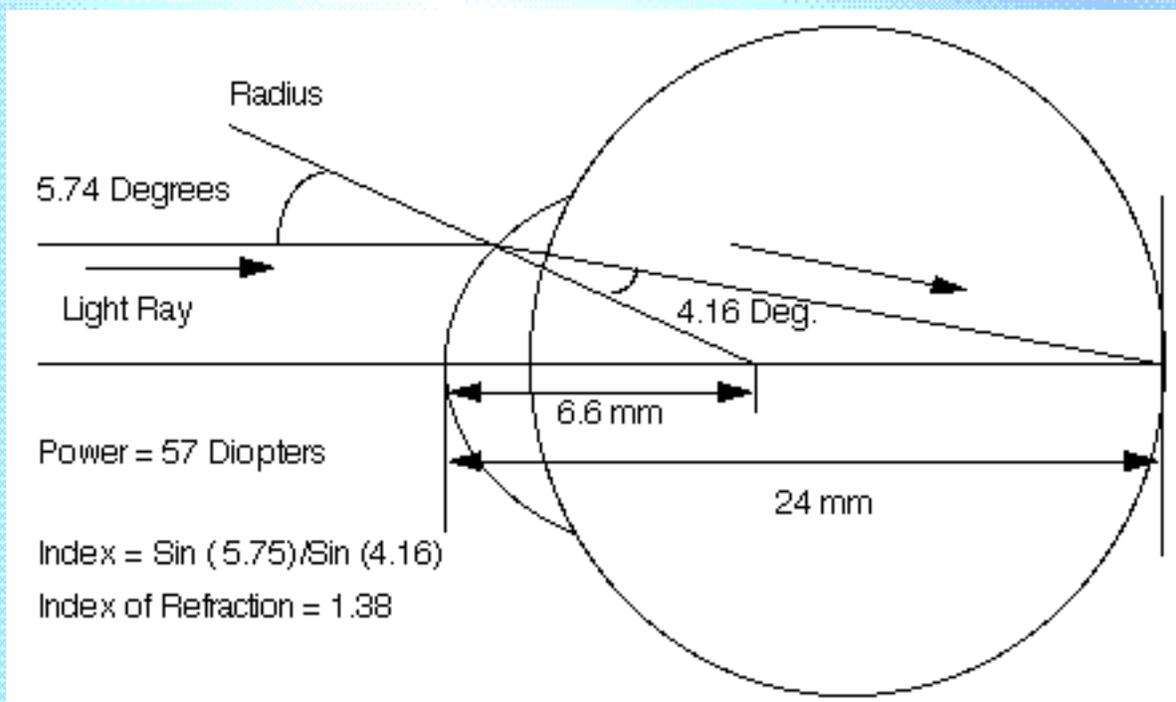

Figure 2 (from Gullstrand's schematic eye, Reference 1).

The distance between the surface of the lens and the point of image formation is called the focal length.

$$\text{Focal Power} = (\text{Refractive Index}) / (\text{Focal Length})$$

By using this equation it is possible to analyze the basic optical properties of the eye. The approximate dimensions of the eye have been established. The radius of the cornea is 0.66 centimeters, the index of refraction is 1.38, and the length of the eye is 2.4 centimeters. By using these numbers we can calculate the focal power of the normal eye. (For reasons of clarity, I have not included the effect of the internal lens. A more detailed analysis can be found in Reference 1.)

$$\text{Focal Power} = 1.38 / .024 \text{ Meters}$$

$$\text{Focal Power} = 57 \text{ Diopters}$$

THE NORMAL EYE

The eye has an internal lens which controls the short-term focal state of the eye. The lens is controlled by blur sensed at the surface of the retina. This information is "fed back" to lens position so that sharp focus can be maintained. (Figure 3)

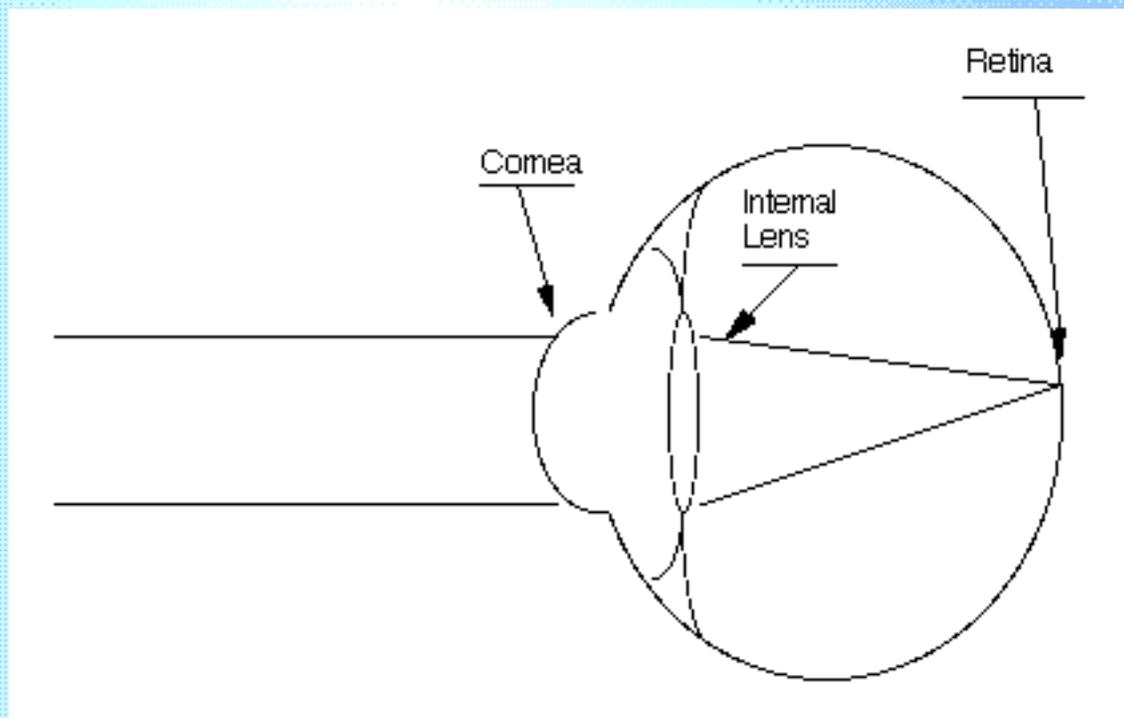

Figure 3.

As objects are moved from distance to near, blur is produced at the retina. In response to this, the lens is thinned or thickened repeatedly under neurological/muscular control, thus maintaining sharp focus on the retina. (Figure 4)

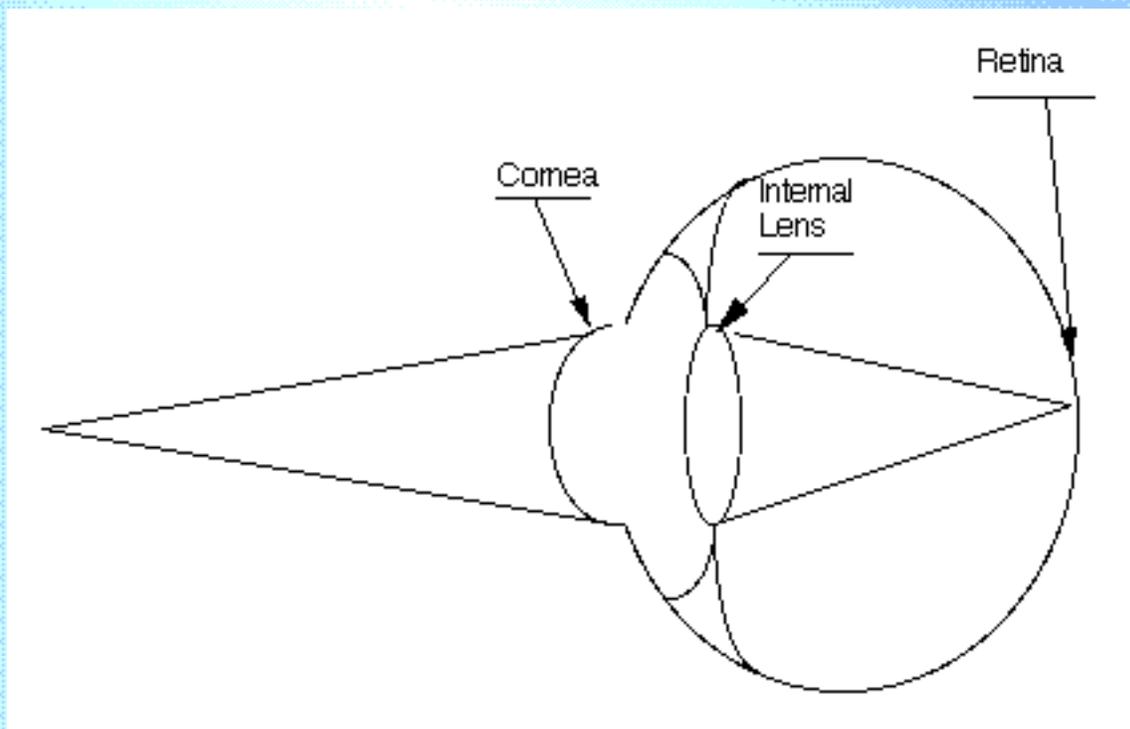

Figure 4.

As we move objects from far to near, the focal change required of the eye increases drastically. Thus the focal change required for an object at 1 yard is 1 diopter. At 20 inches the increase in power is 2 diopters, and at 10 inches the increase is 4 diopters.

The normal eye has a second system which is responsible for controlling its long-term focal state. This system controls both the power (curvature) of the cornea and the relative length of the eye. (Figure 5)

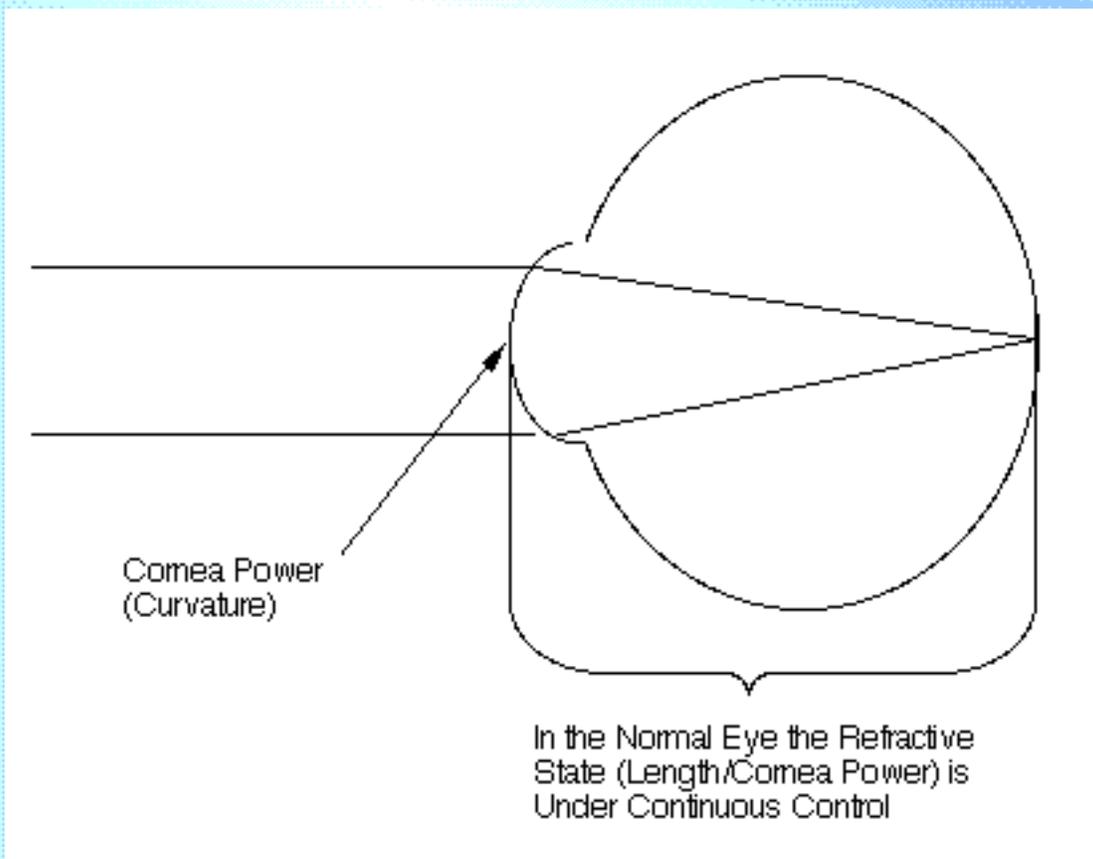

Figure 5.

The normal eye feeds information from the accommodation system to the long-term control system to maintain highly accurate focus. The focal state of the eye is almost a direct replica of its visual environment. By direct experimental means it has been determined that the focal state of the normal eye is equal to its visual environment, offset by about +1.5 diopters.

Whenever the average value of accommodation is shifted by a "delta", the focal status of the normal eye will change, (over a period of months) by the same quantitative amount. This statement has been effectively proven over the last thirty years by thorough experimental techniques. (2)

As the previous discussions have demonstrated, the eye functions as a camera. We should not, however, jump to the conclusion that it is therefore a rigid box camera. It is a sophisticated camera that controls its long-term focus by a "feedback" process. We can use an analog computer to accurately represent this fundamental behavior characteristic of the eye. (Figure 6)

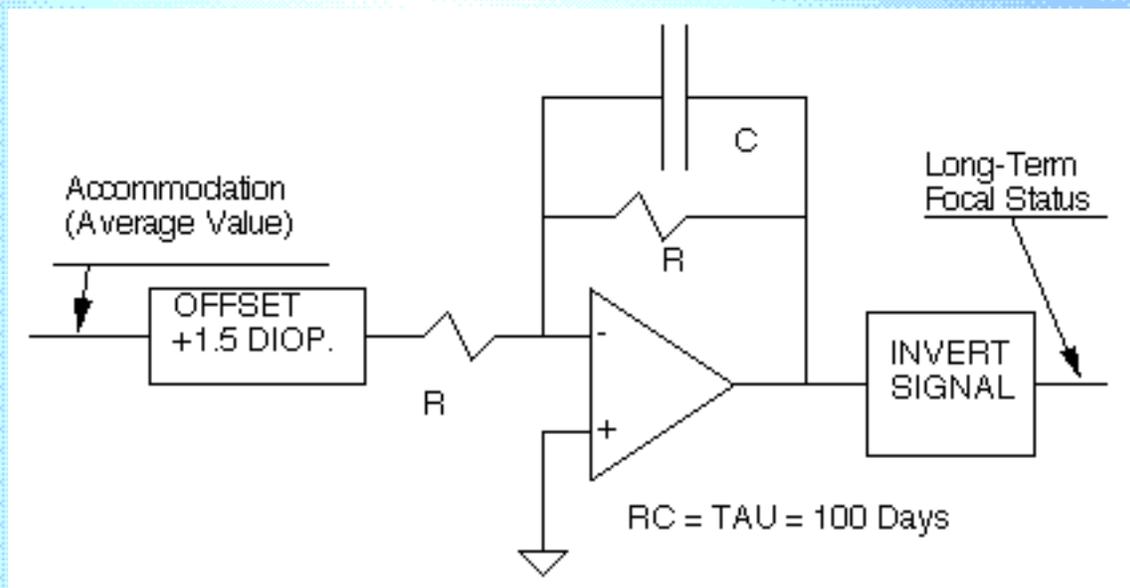

Figure 6.

THIS OPERATIONAL AMPLIFIER WILL ACCURATELY REPRODUCE THE FUNDAMENTAL BEHAVIOR CHARACTERISTIC OF THE NORMAL EYE

The above representation of the normal eye is experimentally valid. When the normal eye is actually tested, it always shows the following two major behavior characteristics. (2)

1. When a strong negative change is made in your visual environment, your normal eyes will change their focal state as shown below. (Figure 7)

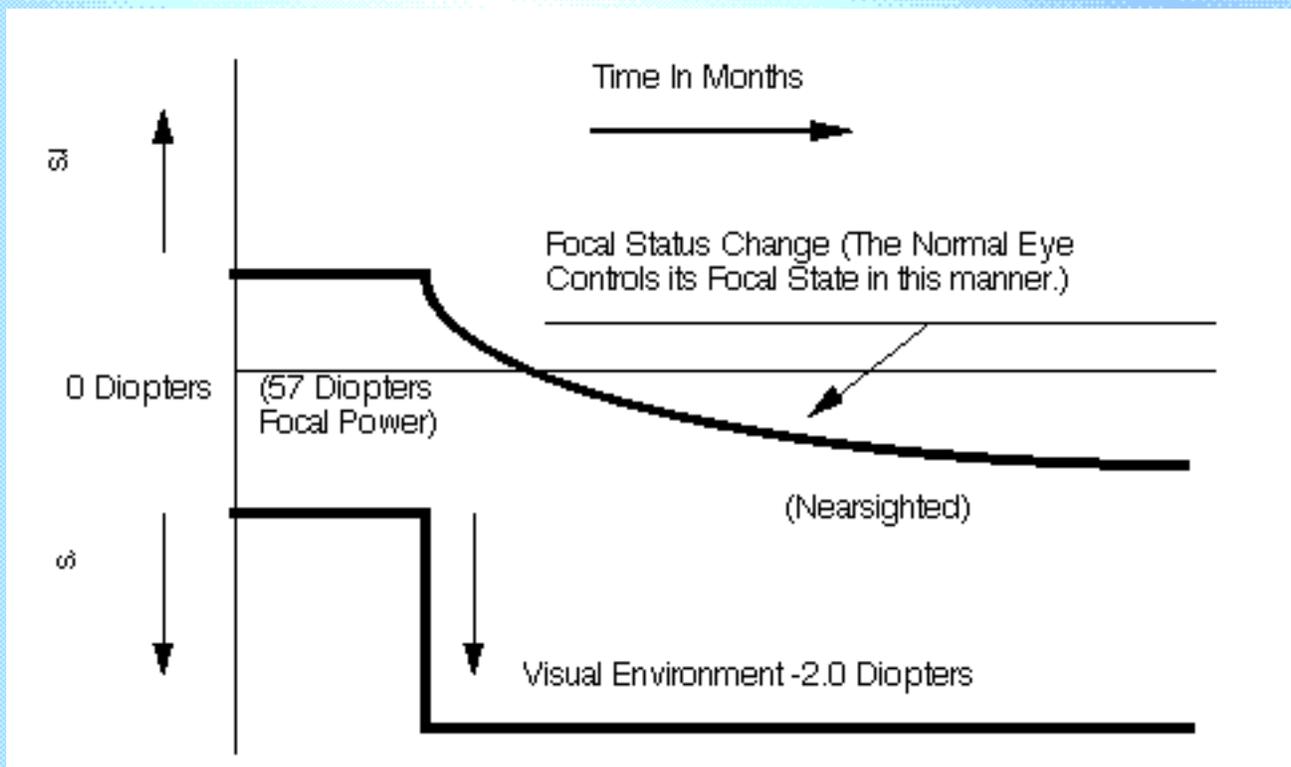

Figure 7.

2. The eye will also show a similar response to a strong positive = change in its environment. There is -- and this is important -- a limit to = the amount by which you can change your visual environment in a positive direction. (Figure 8)

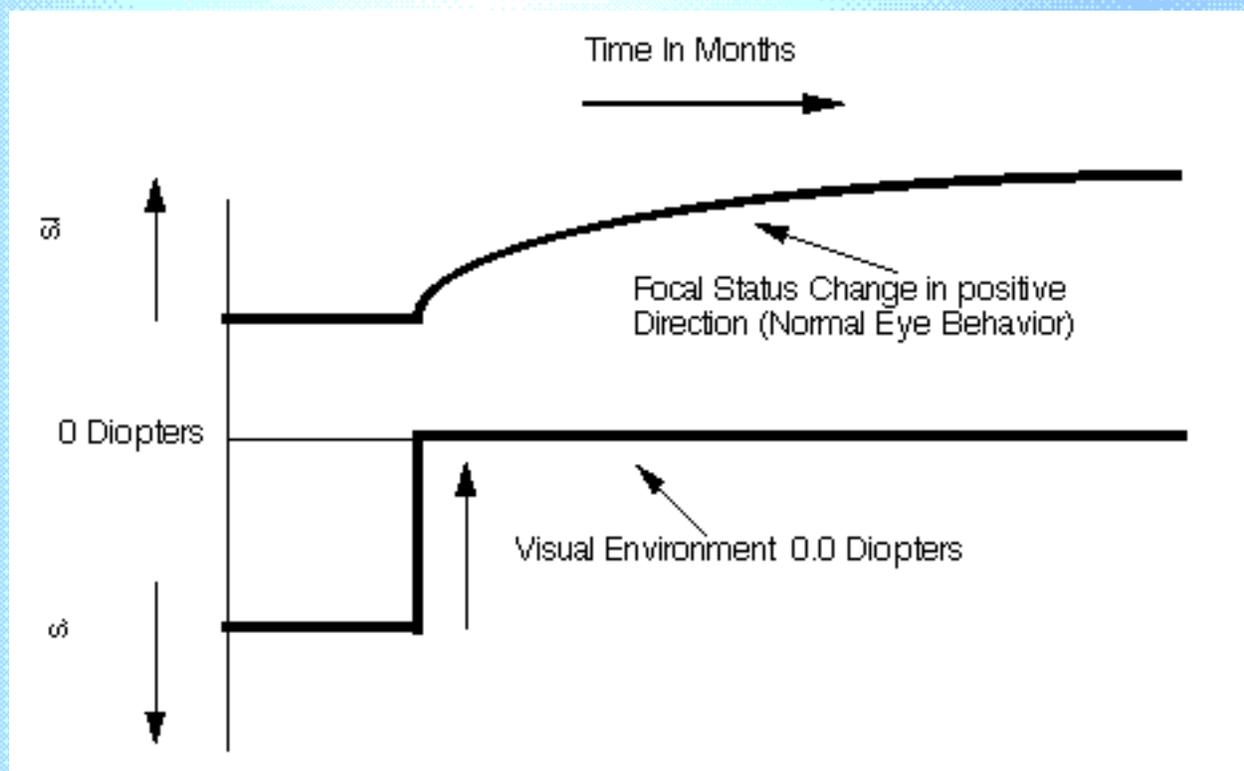

Figure 8.

The conclusion, that the eye is dynamic and behaves as expected, has been reached by a number of scientists. Dr. Peter Greene (5), Dr. Antonio Medina (6), and Dr. Josh Wallman (7) have published papers analyzing various aspects of the time-constant behavior of the natural eye.

CONCLUSION

Perhaps the best assessment of the difficulties and opportunities of nearsightedness prevention was made by Chalmers Prentice in 1895. How many more years will it take us to understand and respond intelligently to the wisdom in his words?

It is common and natural to cling to a belief in things and methods that have long been established, and in which leading men and authors concur; and, if the results of such following are universally perfect, more cannot be desired. But, when they fall far short of satisfaction, we are warranted and even impelled to search outside of established authority for the aid that it fails to give; otherwise, science and art would never advance.

BUT DOES IT WORK?

Thinking is easy,
Acting is difficult,
and to put one's thoughts into action
is the most difficult thing in the world. - Goethe

Men live by their routines; and when these are called into question, they lose all power of normal judgment. They will listen to nothing save the echo of their own voices; all else becomes dangerous thoughts. - Harold Laski

EFFECTIVE RECOVERY AND PREVENTION

The previous chapters have demonstrated, by test, that the eye is dynamic. The eye will change its focal state in a negative direction if placed in a confined environment, and will move in a positive direction (although more slowly) if placed in an open environment. It would be difficult to believe in the opposite possibility concerning the eye's behavior.

Logic, reason and science cannot prevail, until you look at the situation yourself. You must decide that you are willing to make the appropriate commitment to restore your vision to normal. You can achieve what other students, pilots and engineers have accomplished as described in the following letters.

A PROFESSIONAL PILOT RETURNS HIS VISION TO 20/20

Brian Severson was in an engineering college when he began to get into nearsightedness. In previous years Brian observed his brother become seriously nearsighted when he used a negative lens. He had received no information on prevention from the eye doctors he consulted. By his own understanding and perseverance, and some conversations with me, he returned his vision to normal as he describes in the following two letters.

LETTER #1 FROM BRIAN SEVERSON

JULY 26, 1990

Hi! I went out and bought a pair of +1.75 diopter reading glasses, and two days later my vision improved from 20/70 - 20/80 to 20/50 at an exam today. The Doctor wanted to sell me \$500.00 worth of (Band-aid) lenses. What a ripoff!

Please rush me your book. I enjoyed talking to your wife. I will keep you posted on my improvements. Someday when I get a real job that pays more than \$10,000/year I will call and chat with you.

Thanks again,

Brian Severson

P.S. I have a 1st class physical soon and need to improve my vision before then, or send \$156 to my eye doctor for one replacement contact!

LETTER #2 FROM BRIAN SEVERSON

APRIL 10, 1991

I'm sorry I have not taken the time to write or call you until now. On December 4, 1990, I passed a FAA 1st Class Physical and, under much less than ideal conditions, read 20/15 on the eye chart!

Thank you for all you have done to help me. I have at least 15 pilots and friends now wearing reading glasses. I am one-quarter through the rough draft on my vision book, and I am slowly making progress.

Is it still O.K. for me to plagiarize (with credit, of course) from your book? If so, please reply in writing with permission.

Thanks & God bless,

One thing college has taught me is to listen to others and then use or adapt methods to work for me. In the last few years I have had a great deal more reading work to do. If I don't use the magnifying lenses I notice fairly quickly that my sight starts to deteriorate. Then I realize it's time to do something to stop that process.

At the moment, I am wearing the magnifying lens because I know what it does for my vision. Thanks for taking the time to tell me how to avoid a situation, wearing glasses at all times for the rest of my life, that I would find unpleasant, and for sending me a copy of your book so I can learn more in-depth about the methods I am using.

Keith B.

AN ENGINEER'S UNEXPECTED SUCCESS

Perhaps the most surprising and encouraging result to be achieved was accomplished by accident. Because of my long-term experience with the experimental data, I knew that recovery -- on the average -- would be slow. Anyone who attempts to use the plus lens wants to succeed. It makes sense to help people who have gotten into about 20/80. Any improvement will get you to 20/50, which passes the FAA 3rd class flying license. Recovery, if you are worse than 20/100, is difficult but possible. To present all the facts including surprising results, I asked Dennis to write a letter describing his efforts and ultimate result.

VISION RESTORATION: THE EFFECT THAT A POSITIVE LENS HAD ON MY DISTANT VISION

Dennis Romich, July 21, 1992

My distance vision had been poor for many years. I had overheard Otis Brown discussing nearsightedness, and his suggested technique for restoring the myopic eye to normal. Without telling Otis, I decided to attempt to use the plus lens, and see what would happen, since the approach seemed reasonable and much safer than any other method.

I obtained a plus lens at a local store without a prescription. The lens was a +1.5 diopter lens and is commonly sold as a reading glass for people who have lost their near vision.

I had become nearsighted in grade school and was prescribed minus lenses which I dutifully wore all day long. As the years went by, my vision worsened, and the Doctor would

prescribe stronger minus lens. My distance vision without prescription lenses was very bad through high school, college, and graduate school. The last professional check (Ophthalmologist) showed that my prescription was -4.5 diopters (Right eye) and -4.25 diopters (Left eye). This is approximately 20/320 vision using the Snellen eye chart. In some states, I would be classed as legally blind without my glasses.

As I wore the plus-lens and did not wear the minus lens, I noticed that my distance vision began to clear. After several weeks, I purchased Otis' book, and checked my eyes against the eye chart. They were 20/30, which means I will pass the standard driver's license criteria of 20/40 or better without prescription lenses.

Otis was surprised at this effect of the plus lens. He stated that most individuals could return their vision from 20/70 to 20/20, but he felt that returning vision from 20/320 to 20/30 was hard to believe. Since I have done it successfully, I have no doubt that other individuals who have a similar problem could obtain similar results using Otis' recommended method of vision restoration.

I am a registered professional engineer, and have a Master's degree in both Engineering and Business Administration.

COMMENTARY FROM A CONCERNED MOTHER ABOUT THE NEED TO DO YOUR OWN CHECKING WITH AN EYE CHART

AN EXCESSIVELY STRONG PRESCRIPTION?

HOW OFTEN DOES THIS HAPPEN, AND WHAT IS THE LONG-TERM EFFECT AND CONSEQUENCE?

I have retyped this letter from the original and changed the names. Jeanie's daughter started out (at age six) with 20/50. She received a strong minus lens -- even though 20/50 is acceptable for most children. After years of receiving minus lenses stronger than necessary, she received a lens increase from -6.0 to -10.0 diopters. Jeanie's suspicion and response is described in the following paragraphs.

JEANIE BRAVE'S LETTER:

Here are copies of my daughter's eye records and

prescriptions. You will never know how grateful I am for you and Mr. Severson. When I stop and think of what could have happened to Shanna had I not found you -- my blood starts to boil. I have come to realize that people never question eye doctors as they do medical doctors. We are all at their mercy and do not even know it. You have my permission to give my telephone number to anyone who you feel needs it.

A CHECK-UP BEFORE SCHOOL

Shanna received the new contacts on August 5. She puts in -10.0 Diopter and is able to see -- she says one mile down the road. I immediately told her to take them out. After begging my optometrist to please give me information to stabilize her vision, he becomes EXTREMELY UPSET. I then went to the libraries and book stores looking for information but I found only William Bates' name. I then ordered his book. Next I found Mr. Severson and finally you in the back of his book. After reading your books I immediately knew I had the wrong optometrist -- so I nicely asked his assistance in obtaining a -6 Diopter lens for studying. The doctor reluctantly gave them to Shanna, telling us to use them for STUDYING ONLY. I then confirmed the focal status of Shanna's eye's, by assisting her in checking her vision against the eye chart -- both inside and outside.

8/26/95	20/20	-8.0 RE	-7.5 LE	
8/26/95	20/100	-6.0 RE	-6.0 LE	(Provided for reading)
8/31/95	20/40	-6.0 RE	-6.0 LE	
9/26/95	20/20	-6.0 RE	-6.0 LE	(See the -10.0 D prescription below)

Since she was seeing so well on 9/26/95, I told her to remove her contacts and then come back outside. Without ANYTHING on she stood 20 feet away and could focus on the 20/70 and 20/50 line for about 2 or 3 seconds -- then she said it would flash or float away.

An Excessive -10 D Prescription?

Prescription by Dr. Bob Smyeth, Optometrist, Dated 8/5/95:

Patient: Shanna Brave, Birth Date, 3/2/82:

8/5/85	20/20	-10.0 RE	-9.5 LE	(Prescription)
--------	-------	----------	---------	----------------

In subsequent conversations with Jeanie, she stated that her nine year-old son was just starting into nearsightedness, and that she would do everything in her power to help her son with the proper use of the plus lens -- to avoid the catastrophic situation that had developed with her daughter. Jeanie wondered why this knowledge is not made generally available to the parents of young children.

YOUR MOTIVATION IS CRUCIAL IN ORDER TO DEFEAT MYOPIA

It is clear that an intelligent, motivated pilot or student can use the plus lens for close work, check his eyes against the eye chart, and clear his vision back to normal.

What is the opinion of this situation within the eye profession? Opinions vary, as shown in the following exchange in the Washington Post newspaper.

IS IT TRUE THAT THE EYE DOES NOT CHANGE ITS FOCAL STATE WHEN PLACED IN A CONFINED ENVIRONMENT?

Myths About Problems With Poor Eyesight

[Special to the Washington Post, 9/11/91]

Dr. Jay Siwek

Q.

My family likes to watch TV at night with the rest of the room lights off. But a friend told me that watching TV in the dark is harmful to your eyes. Is this true?

A.

You can't harm your eyes by watching television in the dark. Neither can you damage them by reading, working or studying in dim light. Those are some of the many myths about why eyesight deteriorates.

Another folk belief is that "using your eyes too much" will harm vision. That's nonsense. Your eyes were made to see with and, barring some medical problem, they don't wear out from use.

Some people also believe that looking at objects close-up will impair vision, especially if done for long periods of time. Not true. Again, vision doesn't deteriorate from fine use. It's easy to see how some of these myths came about. In days past, before doctors knew about eye diseases like glaucoma, cataracts and macular degeneration, people looked for some explanation whenever someone lost their vision. Glaucoma is increased pressure in the eye, and cataracts are a clouding of the lens of the eye. Macular degeneration is a condition

where the center of the field of vision deteriorates.

Often, blindness or low vision was blamed on someone's work, such as writing or reading by candlelight or on simply using one's eyes too much.

Common eye diseases frequently struck people who did fine work with their eyes, leading to the belief that there was some connection between the two. People tended to ignore the many examples of people who didn't develop any problem with their eyesight or of all the people who lost their vision for no apparent reason.

As people age, they sometimes have trouble focusing on fine print that's too close to their eyes, a condition called presbyopia. But scientific studies don't show any link between the way you ordinarily use your eyes and harming your vision. So, you and your family don't have to worry about watching TV in the dark.

IS IT TRUE THAT THE EYE DOES CHANGE ITS FOCAL STATE WHEN PLACED IN A CONFINED ENVIRONMENT?

The Health Profession's Response to "Problems With Poor Vision".

Dr. Robert Levy:

I must strongly disagree with at least one "myth" about poor vision Dr. Jay Siwek mentions [Consultation, 9/11/91]. He says doing close work does not harm your eyes and then goes on to talk about three sight-threatening diseases. While it is true that close work does not cause the kinds of blindness that glaucoma, cataracts and macular degeneration do, such fine focusing for extended periods can cause nearsightedness, a far more common occurrence.

Day after day, year after year, I see patients who get more and more nearsighted from doing close work, particularly if they have been wearing a distance prescription while doing their close work. The vicious cycle is that you read and do your homework, become nearsighted, get distance [negative lens] glasses and when you go back to read and do your homework you become more nearsighted.

People who take their glasses off to read (if they can) or who wear bifocals [plus lenses] to reduce the prescription for near focusing show a much slower progression into nearsightedness than those who read with distance glasses on. One study of an Eskimo village being taught to read showed that after two generations of reading, virtually none of

the grandparents' generation needed distance glasses, about half of the parents' generation did and virtually all of the children's generation did. This is the best example of reading and close work causing nearsightedness.

A COURAGEOUS EYE DOCTOR DOCUMENTS THE SECONDARY EFFECT OF USING A NEGATIVE LENS

EYESTRAIN - ITS CAUSES, CONSEQUENCES AND TREATMENT

By Dr. Maurice Brumer, Frankston, 3199, Australia

. . . A succession of practicing optometrists have followed Fournet [a pioneer in the use of the plus lens] to this day, all convinced of this major shortcoming [use of a negative lens] in eye care. They have all been successfully ignored or treated as cranks and heretics, and the issue has remained at this level for 90 years. The clarion cry of the eye care professions has been "show us proof of the relationship of eyestrain and eye disease". I will now demonstrate that no shortage of this proof exists.

At the 1973 annual meeting of the American Academy of Optometry, a paper entitled, "Bifocal Control of Myopia", was presented by Francis Young, Director of the Primate Research Center at Washington State University, and Kenneth Oakley, an ophthalmologist from Bend, Oregon. Their study found that the effects of properly fitted bifocals (eye strain reducing glasses) on young myopes are to drop the rate of progression of this condition from an average of about one half a diopter per year to about one fortieth of a diopter per year. This study involved control and experimental subjects who were matched for age, sex, initial refractive error and duration of wearing bifocals so that most of the possible causes of failure to achieve results with bifocals were controlled.

THE BIFOCAL (PLUS LENS) STUDY

There was a significant number of subjects, 226 in the bifocal group and 192 in the control group, to assure that the results were consistent and effective over time. The effect of the bifocal was uniformly to reduce the rate of progression even in children who had already achieved as much as 4 or 5 diopters of myopia before they were fitted with bifocals. In other words, the control group moved into myopia at a rate 20 times faster than the bifocal (plus lens) group. The implications of such results are obvious and sinister when it is considered that myopia is the third largest cause of blindness in western society.

SERIOUS COMPLICATIONS DEVELOP FROM USING A MINUS LENS

The visual disability in high myopia is usually considerable. I am including this description of the condition as felt by its victims so that you may put yourself in their situation:

Apart from the visual incapacity, the high myope is not usually comfortable in the use of his eyes. When corrected, the small, sharply defined and bright images are annoying; much use of the eyes brings about a feeling of strain and fatigue. The degenerated and liquefied vitreous gives rise to a multitude of "muscae volitantes" and floating opacities, and these, throwing abnormally large images upon the retina owing to its backward displacement, cause a great deal of distress and anxiety to the patient although their actual significance is small. Most of these patients are naturally anxious. Their disability is obvious and may have excited sympathy. The memory of admonitions to care for the eyes lingers into adult life. Thus matters tend to progress slowly and relentlessly, the patient all the while never using his eyes with comfort or without anxiety until finally no useful vision may remain or until the occurrence of a sudden calamity such as a gross macular lesion, a hemorrhage of a retinal detachment brings about a more dramatic crisis. (I thank Sir Stewart Duke-Elder for this description).

The complications of myopia are numerous and grave, frequently resulting in blindness. The degenerative changes appear typically in adult life after the myopia has been fully established for some years.

The complications are:

1. Choroidal thrombosis and hemorrhage.
2. Vitreous opacity, always present in some degree in high myopia, this condition may suddenly increase to become a serious complication.
3. Retinal detachment is the most dreaded and one of the most common complications of myopia, occurring with considerable frequency in = all degrees of the defect but showing a progressively greater tendency, the higher the myopia.
4. Simple glaucoma is a further complication of high myopia, occurring = in the higher degrees after mid-life.

THESE PROBLEMS COULD HAVE BEEN PREVENTED

Few of these people faced with the prospect of blindness in old age realize that their problems actually began in childhood when they were fitted with their first pair of corrective [negative] lenses by someone who was probably unconcerned about the tragic, long-term results of that action. Few of these people realize how their situation became more precarious each time their glasses were strengthened and nothing was said about prevention. Now, when it is too late for prevention, they find themselves in the hands of surgeons who are making their living from someone else's mistakes by trying to patch up steadily deteriorating retinas. The patient has become a lifelong victim of ignorance and

exploitation.

THE EYE CHANGES FROM A POSITIVE STATE TO A NEGATIVE STATE AS A RESULT OF CLOSE WORK

The cause of myopia is further clearly indicated in a study of 1200 Eskimos in Barrow, Alaska, published in the American Journal of Optometry in September, 1969, which showed that in one generation of the Eskimo population had moved from no myopia to approximately 65% myopia among the offspring, and that neither the grandparents nor parents over 40 had any myopia.

Thus the first generation between grandparents and parents was similar in that myopia was nonexistent, but in the second generation between the parents and their children, suddenly myopia occurs in a surprisingly high number of children. As a matter of fact, of 53 offspring who were in their early 20's, 88% had myopia. Such a sudden and great degree of change cannot readily be accounted for on the basis of heredity, especially when there has been no identifiable force which could have brought about this obviously considerable mutation in the genetic composition of the offspring.

The obvious difference between the parents and the children is the amount of near work which is currently being done by the children. About the time of the second World War, the white man intruded into their lives, requiring the development of education among a population which was uneducated and illiterate. The Eskimo has become an avid reader because of his environment. While he spends a great deal of time out-of-doors in the warmer, daylight summer months, he spends relatively little time out- of-doors in the cold, dark winter months.

A MASSIVE BODY OF EVIDENCE SHOWS THAT THE EYE CHANGES ITS FOCAL STATE TO MATCH ITS VISUAL ENVIRONMENT

In presenting these studies, I would emphasize that these represent only a small (even if spectacular) part of the evidence available today which demonstrates the blindness and suffering caused by present-day eye care. While continuing to ignore a massive body of evidence, the eye care professions continue to ask to be shown proof that myopia results from excessive close work and that the prescription of corrective lenses causes the myopia to increase more rapidly than it otherwise should. It is assumed from the start that the burden of proof is on us and that we are expected to raise money and conduct endless studies that will somehow convince everyone that we are right. In many cases, this is like trying to convince a tobacco company executive that smoking causes lung cancer. No amount of testing will convince those people who prefer to believe what pleases them most or what is more lucrative to them. . . .

[Dr. Brumer reviewed an exchange of letters with a Dr. Lender (a university optometrist)

concerning disagreement about the fundamental behavior characteristic of the eye under experimental test conditions.]

. . . These letters represent a desperate attempt to cover up a tragic and horrible situation. They mislead the public and, significantly, the parliament of my country. They have been unsuccessful in their purpose, however, and the question now lies on notice in the parliament in Canberra to the Minister of Health for Dr. Klugman (opposition spokesman for health) asking him to appoint an inquiry into the matters I have raised.

THE EYE PROFESSION RESISTS CHANGE -- TO YOUR DETRIMENT

The eye care professions have resisted change irrationally and fearfully, unwilling to admit that what has gone on before [the use of a negative lens] has been wrong and harmful, and by doing so they have unleashed on the public they serve a cataract of horror. This continued situation is a tragedy for the public and a disgrace for optometry. While it is understandable that optometrists will not find it easy to admit that what they have been doing is wrong and harmful, especially for those academic university optometrists responsible for the education of our graduates, to preserve the current horrors to protect our professional prestige and privilege is an abdication of our responsibilities, ethics and morality. I can make no apology for causing embarrassment to my professional colleagues. The interests of the public are paramount and must be served. The purpose of this paper is to direct the future to end the disgrace of the past.

REMARKS ON DR. MAURICE BRUMER'S PAPER

Dr. Brumer had previously been denied permission to present his paper at the August, 1977 Australian and New Zealand Association for the Advancement of Science (ANZAAS) Congress because it was too critical of the prevailing method of eye care. The above paper is of interest because of Dr. Maurice Brumer's scientific and ethical commitment to:

1. Coming to grips with nearsightedness. (i.e., The fundamental = behavior characteristic of the eye.)
2. The reaction of other members of his profession. (Extremely = critical -- without clear scientific justification.)
3. The reaction of the public to Dr. Brumer's effort to come to grips with the situation. (Nonexistent -- because the public was not clearly informed.)
4. The fact that this understanding (that the plus lens works) existed = in 1977, and since then, nothing further has been done to provide = pilots with the high quality information they need so that they can take = the steps that are necessary to preserve their distant vision for life.

THE INTERNATIONAL MYOPIA PREVENTION ASSOCIATION

From, "THE MYOPIA MYTH", by Donald Rehm

In 1974 Donald Rehm established an organization to help parents understand and take steps to help their children avoid myopia. He prepared a book that clarifies the various preventive methods available for myopia -- and the reaction of most of the profession to his efforts. Donald describes his effort to persuade the profession to provide you with exact knowledge of the eye so that you might capably choose between these mutually exclusive alternatives.

. . . Since the organizations in the eye care field were telling the public nothing about the true cause of myopia, the idea of forming an organization devoted solely to myopia began to seem more and more necessary. The final decision about forming a myopia prevention organization was made at the 1974 Annual Congress of the American Optometric Association in Washington, D. C.

An important part of such meetings takes place on a large floor where booths can be rented to exhibit optical goods, hand out literature, etc. I rented a booth to give out literature on the latest research on myopia and ways of preventing it. I found that the booth was for the most part ignored by most of the optometrists, although an adjoining booth, where the tinting of eyeglasses was being demonstrated, was usually crowded.

It was obvious that the people to whom we must go with our vision problems were more interested in tinting lenses than in saving sight. They were ignoring everything that had to do with myopia prevention. It was quite clear that pleading with the members of the eye care professions to change their ways was not going to succeed. They would have to be forced to change, and this would occur only after the public was well informed about the real causes and solutions to the problem of myopia.

In 1974, I therefore formed a nonprofit, tax-exempt Pennsylvania corporation, the International Myopia Prevention Association. One of the first tasks I undertook was the publication of a twelve page booklet, *The Prevention of Acquired Myopia*. This booklet, which was meant for distribution to the public, contained information on the real cause of myopia and what methods were available to prevent it. No booklet of this type had ever been published previously. In the booklet, I also stated the aims of the new organization:

1. To work for the widespread acceptance of the concept, now supported by numerous studies and research, that acquired myopia is caused by excessive close work and is not an inherited condition.
2. To inform the public, in an impartial manner, about the various methods available for preventing and controlling myopia.
3. To promote periodic testing of the vision of children so that the potential and beginning myopes can be found early when treatment is most effective.
4. To promote the use of proper reading habits and adequate lighting in schools, homes

and offices.

5. To maintain a register of eye care practitioners who are interested in myopia prevention and skilled in its techniques. *
6. To assist the public in coming into contact with these practitioners. *
7. To issue a periodic publication to provide a summary of activities and new knowledge in this field.
8. To maintain an advisory board of scientists, researchers, educators, optometrists and ophthalmologists who are involved with the myopia problem and can advise on the activities of the association.
9. To solicit contributions to carry on educational and scientific activities related to myopia prevention." *

As the formation of IMPA was announced in various optometric journals (it was ignored by the medical journals), I began to receive letters from doctors around the country expressing their interest in the new organization. The response was greater than I had anticipated and indicated clearly that there did exist an unfilled need for leadership in the area. . .

* In a later publication Donald Rehm sadly concluded, "We no longer try to maintain a list of prevention minded eye doctors since there are so few of them."

WHERE CAN I OBTAIN DONALD REHM'S BOOK?

The International Myopia Prevention Association
1054 Gravel Hill Road
Ligonier, PA 15658
<http://www.myopia.org>

Donald's book may be obtained by ordering it through the above address. Please check his web site. Eyeglass wearers take note: The book, "The Myopia Myth -- The Truth About Nearsightedness and How To Prevent It", will undermine all that you have been led to believe about nearsightedness. Writing in matter-of- fact language and using some fifty simple, clearly marked diagrams, Donald Rehm presents a comprehensive over-view of just about everything you might want to know about myopia: prevailing myths about the subject (propagated, in large part, by your own eye doctor), real and fictitious causes of the problem, proper and improper methods of treatment, and how to know if your eye doctor is really helping you.

OTHER PUBLICATIONS

- THE STRUCTURE OF SCIENTIFIC REVOLUTIONS by Thomas S. Kuhn Provides a fundamental discussion of scientific principles, and the development of paradigms as they support the basis for accurate scientific research.

- **NEUROLOGICAL CONTROL SYSTEMS** by Howard T. Milhorn Explains the application of control theory to physiological systems.
- **INTRODUCTION TO PHYSIOLOGICAL OPTICS** by J. P. C. Southhall Provides = a purely optical theory concerning the eye. This is the standard text book with a major part of the optics derived from a treatise by Herman Helmholtz.

Beyond this point, your own ability to make a good judgment of the situation must be your guiding light. No one should dictate what you should or should not do. We can only assist you in understanding the facts -- so that you may make a reasonable decision about what course of action best suits your own personal needs.

This article was posted to USENET newsgroup sci.med.vision on Dec 11, 1995. It was originally found on CompuServe.

I Can See

by Adam Klein

PREFACE

This is the story of how I learned to see clearly without the aid of refractive (usually called corrective) lenses. I write it because I feel a duty to inform as many people as I can that improving one's naked eyesight is a real possibility despite the skepticism of the eye care professional world. I will refer to such apparently unrelated subjects as singing, memory palaces, high-tech catalogues, myofascial trigger points, yoga, diet and pinhole glasses in order to show how these things combined in my life to allow me to shed the crutch of eyeglasses, and so some of those who read this will be encouraged to try for themselves, or keep trying.

INTRODUCTION

For centuries, no one from Europe sailed past the western tip of Africa for the simple reason that they had been told with no room for doubt that the world ended there and they would surely perish if they passed it. The feelings I experienced the first time I encountered success in the retraining of my eyes must be similar to those felt by the sailors of that first ship that saw the southwest African coast. An elation that despite everything I'd been told all my life it was truly possible, though at the time I had no idea how far I'd be able to take this journey, that is, if I'd ever see clearly all the time. A deep anger at the fact that I hadn't found out about it sooner, because almost no one knows about or believes in these techniques, and because due to my ignorance my social life during the nineteen years I wore glasses was almost certainly much lonelier than it would otherwise have been. Those who don't wear glasses as children and teenagers have no inkling of the psychological effect imposed on the children by the wearing of these things. We are branded as nerds, brainy misfits, unathletic "spazzes," to use the slang of my day. When I learned, through personal experience, that most children wouldn't need glasses if these techniques were learned, understood, standardized and disseminated, the ostracization of all these children as being no less different from what is called normal than being of another skin tone or sexual preference became to me a heinous crime, a perpetratorless, victim-replete crime. Thus it is for those like me, of all ages but especially those as yet unborn, that I must tell my story, in the hope that in the future the techniques of eye training will be taken seriously and become a part of the eye care arsenal in the war against blurred vision. I have nothing to sell; I consider awareness of this information to be a right of all those not diagnosed at 20/20.

MY UNWITTING PREPARATION

I learned some Hatha yoga techniques when I was eight years old. The degree of body awareness it gave me has proved extremely useful in my adult life. One technique, a breathing exercise, in part requires the person to relax all the muscles in the body (besides the ones needed for sitting up) by noticing tension and releasing it. This is done in conjunction with regulating the breath with the intention of slowing the heart rate (which many medical practitioners will argue cannot be brought under voluntary control) and generally relaxing the body. Years later, when I learned the techniques of operatic singing, I was able to apply this relaxation technique by noticing and releasing tension in muscles not necessary to the production of an efficient tone. (Many opera singing techniques pay little attention to the fact that there are many sets of muscles in the laryngeal area, and very few are needed for singing. The great diversity of tonal color among singers is due to the many possible combinations of muscular action by which one can make a sound, each of which will result in harmonic structures predictably different from the others.) The difficulty in singing is that the muscles used to phonate are not directly controllable, like the heart rate. One must find ways around this obstacle of inaccessibility through mental images designed to get the muscles to act properly, and of course through audiofeedback. For ten years daily I practiced these concepts guided by my teachers, and my voice underwent many changes in size, timbre and sustain ability, some drastic. I thus became accustomed to searching for a sound that initially would have been unimagined in my mind or ears, but would, when the proper muscular combination was used, often accidentally, suddenly make itself manifest. Because of this constant change in the sounds I was able to produce, I learned to dissociate the sound of my voice from my personality, which some singers and many nonsingers never do, and by extension to dissociate all other aspects of my physical being from my personality, excepting of course those attributes innate to my sex, whatever they may be. Through this experience I came to understand on a personal level that things are often not as they seem.

In 1983 my father was diagnosed with lymphoma, and because of the dismal forecast given him about his life by the doctor who diagnosed him, he sought an alternative cure. Through this search of his I became acquainted with the Hippocrates Health Institute, which promotes a cure for cancer through a diet of only raw, alkaline-reaction-inducing foods. Though several people had been helped back to health by this diet, my father's version of it eventually failed and he underwent chemotherapy, but due to the year on this diet his body was much stronger and better able to withstand chemo's chemical onslaught, and in fact he never lost his hair, even when he was given the drugs he was assured would make it fall out. (Also, the cancer in his bone marrow at his first biopsy, before the diet, had somehow disappeared by the time he decided to undergo chemo.) This adventure taught me that the medical community, no matter how much they insist we submit to their care, actually know very little about the workings of the human body. The nutritional industry is similarly sailing equally uncharted waters. I became predisposed to distrust these and other authorities when it comes to proclamations concerning the abilities and inabilities of the human organism.

In 1972 I got my first pair of glasses. I had resisted them for a year, saying I didn't need them, but once I got them I wore them constantly, except to see closely. It bothered me that every time I had a checkup my eyes had slipped a little more into myopia, starting at 20/70 and ending at my last checkup in 1984

around 20/300. (20/70 is "legally blind" in New York State.) I was never given more of an explanation for this decline than that it was a normal progression for myopes. When I took genetics in high school and college, I began to wonder why I was the only myope in my entire family, including parents, both brothers, uncles, aunts, and cousins. Genetically this made no sense to me. So for years I doubted the eye care industry's claim that my condition was unchangeable, but I found no concrete substantiation of my suspicions until 1991.

In 1989 I was led to the book "The Art of Memory" by Frances Yates through my participation in an avant-garde opera by Robert Ashley, "Improvement: Don Leaves Linda" which refers allegorically to Giordano Bruno and memory systems, and through my acquaintance with one Philip Guerrard who was familiar with Yates' books on these subjects. The art of memory is a technique of using imagery as an aid in the memorization of speeches by ancient Greek orators. It involves building structures, e.g., houses or palaces, in one's imagination, to house images chosen for the ability of their attributes to remind one of an idea, phrase, or even a word. The theory is that since humans depend so much on visual information, it should help in the retention in memory of such abstract things as words or ideas if one links images to them, preferably striking images. I tested this on myself, and made a house for all the jokes I knew, since I had long been annoyed by my inability to remember all the jokes I knew at parties or on long car trips with new acquaintances. It works. I can now at will call up from memory any one of over fifty jokes simply by mentally looking through the house I used and seeing the representative objects I placed there. I then used the art to help me remember all the important facets of my vocal technique, which was easy since many of them were images already. I thus became able much more quickly to figure out which part of my technique I wasn't paying enough or any attention to when I was having vocal trouble. This made me better prepared to improve my eyesight when those techniques useful to me asserted themselves over the other ones not specific to my personal psychomuscular makeup. I made a house for them as well, some images of which are described later.

MY CHANCE EXPOSURE

In 1991, I was singing the role of Don José in Philadelphia, and I glanced at a Hammacher-Schlemmer catalog that a chorus member had brought to rehearsal to alleviate the tedium of waiting for a chorus scene to be rehearsed. In the catalogue was an ad for "aerobic glasses," made of opaque plastic and studded in a honeycomb pattern with pinholes. It advertised seeing clearly without using lenses and improving eyesight. The concept of pinholes was familiar to me: before I allowed myself to wear glasses I had discovered that I could see better if I formed a small hole with both pairs of thumbs and index fingers and looking through them. I ordered the "aerobic glasses" at an exorbitant price (\$40.00; I later saw the same thing in a health food store in Iowa for \$25.00. They're worth about 50" in material, if that.) and received them at my next job, which was Faust in Durham NC. I wore them and shared them with fellow cast members, who were amazed at the effect they produced. Almost everyone who tried them could see fairly clearly, and what amazed them was that it could be done without lenses of any sort.

With the "glasses" came a booklet called "SECRETS OF SEEING WITHOUT GLASSES OR CONTACTS" which described exercises to do to strengthen and relax the muscles around the eye, a

schedule for wearing the "glasses" and also a reference to one Dr. William Bates, on whose original techniques the writers of this pamphlet had allegedly improved. I mentioned that name to the woman playing Marguerite, Kay Lowe, and she said she had his book. I borrowed and read it. The pamphlet writers had not improved on Bates' technique, only added others, and actually misrepresented some of the most important exercises.

Dr. William H. Bates, M.D., wrote his book "The Bates Method for BETTER EYESIGHT WITHOUT GLASSES" in the early part of this century, and it was published by Emily Bates in 1940. Bates, who died in 1931, was an ophthalmologist in the New York area who taught himself to overcome his presbyopia ("farsightedness") and then proceeded to refine and augment the techniques he developed for himself to help others to learn to see without the aid of lenses. (The book is still available for purchase. (It is an "Owl Book," published by Henry Holt, New York.) It was during my reading of the chapter "Imagination as an aid to vision" that I first experienced the possibility of long-lasting vision improvement.

The book described a process of observing a letter at a distance at which it appeared in clear focus, then using memory of the letter to imagine it clearly while viewing it at distances at which it would not be seen clearly (in my case, farther away). One could increase the distance in small increments, as Bates had one woman do. I applied this technique immediately after reading it to a few whole words on the page I had been reading. It worked. (It must be emphasized that I read the book with my unaided eyes. I believe it would do no good to read it while wearing glasses. because one couldn't then immediately try out the various exercises described.) I held the book farther away by degrees until I was seeing the words clearly at a distance twice that at which I had been able to see clearly with my naked eye for the past decade and a half. By the time that gig ended I was able after some practice to read book spine titles on my TV eight feet away. The first title I read this way was "Wonderful Life" by Stephen Jay Gould. I am not a believer in fate or occult connections between things, but that title was appropriate, I thought.

Some of the explanations in Bates' book for various eye problems have been superseded by modern advances in methods of physical examination and a better understanding of the behavior of light. But his techniques for relaxation of the eye musculature have not, to my knowledge and in my opinion, been significantly improved upon.

THE TECHNIQUES

The techniques in Bates' book which I found most helpful to me (it must be understood that eyesight, like singing, is a highly psychological endeavor and no one set of images will work for any two people, let alone everyone) were: Palming, Shifting, remembering the color black, never staring at any one point for more than a second, and using the letter chart provided with the book to help relax the eye muscles (not the ciliary muscle, the ones around the eyeball, the ones responsible for moving the eye around. They can not be felt when they're contracting and I discovered that mine had been locked in a certain combination of tension for many years, which had increased incrementally by each checkup). Please read his book to learn about these techniques in detail. The arcane writing style and the quaint naïveté of someone writing

before television can nevertheless be digested. I will describe here the tricks I've discovered myself that are not described by Bates.

THE NECK CONNECTION

My next gig after FAUST was in Chautauqua NY, where I attended a lecture by a trigger point specialist, which is someone who alleviates muscular pain such as headaches by application of an understanding of the relationships between incorrectly contracting muscles and pressure points called trigger points that if properly massaged bring about a release of the offending tension. His live demonstration on singers he had never before met convinced many of us that there was some substance behind his radical rhetoric, and convinced me that his reference book "Myofascial Pain and Dysfunction: The Trigger Point Manual" would be worth having. (He wore glasses, and I asked him if he'd heard of Bates, and he said yes but didn't seem interested in applying it to his own field. I found it curious that even someone as far from the medical mainstream as a trigger point specialist, and someone who constantly worked to relax others' muscles, should show such little interest in improving the function of his own eye muscles.) I bought the book through the local bookstore at home. It is a user-friendly reference guide to alleviating muscle problems by the use of diagrams showing the many trigger points and which muscles they affect. It led me to wonder if there were eye-muscle trigger points, and several months later I discovered one while on a long car trip.

Once I learned to see clearly fairly often, around 40% of the time (and the rest of the time was never nearly as blurry as it had been when I wore glasses) I was able to drive with unaided eyes, except at night when my eyes got tired and it became more difficult to relax them. (Since then I have become able to drive quite late into the night with unaided eyes.) One evening I began to massage the neck muscles at the base of the skull. I found that if I held pressure on these muscles my eyes would involuntarily see more clearly. It took several more months for it to occur to me that I didn't need to constantly hold my fingers to my neck to see clearly more easily, that the same result could be achieved by using muscles on the other, anterior, side of my neck to counterbalance the pull of these rear muscles and relax their hold on my eyes. The memory image I use for this is a seahorse, because of the curvature of their heads and necks. When I use the muscles in front of my ears to rock my head forward and loosen those rear neck muscles, it feels like I'm imitating a seahorse.

BLINKING

When I first started learning to release the ocular tensions accrued over the years, my yoga background was invaluable. I soon became aware of many theretofore unrecognized tightnesses in the eyes brought on by various actions. One of the very first I noticed was a tension brought on by blinking. This is difficult to describe, and I must use image metaphors. The way I learned to blink had a feeling associated with it similar to the action of pulling shut a long trapdoor than was suspended by a spring at the free end, and pulling it from a position about halfway down the length of the door. Another analogy would be using one's foot to depress a spring-loaded organ or synthesizer volume pedal. Or simply pushing down a

cafeteria-type spring-loaded dish holder mounted on a table the surface of which is at shoulder height, with the tips of one's fingers from as far away as one could reach, keeping the arm perfectly straight. If you can keep one eye wide open and the other shut but not at all squinting, they way you keep the eye shut is the way I used to blink. This way of blinking, I found, caused my eyes to blur a bit, and I quickly started blinking more, as it were, with the front muscles of the eyelids, those muscles employed when one shuts the eyes tight while also raising and stretching the upper lip in a smiling grimace. It would be like going to the free end of the trapdoor and pulling down gripping the edge with the palm side of your forearms facing you. Or using your thumbs an the very end of the organ pedal instead of your whole foot along its entire length. Or just sitting on the plates. It was a very noticeable blink and resembled a nervous twitch. Gradually I allowed myself to blink in a more normal-looking manner, but without the old blurring tensions. I use the large "front blink" now only when the other techniques aren't helping, or when time doesn't allow more effective but slower techniques like shifting. The memory image I use for this is the old Porky Pig, way back before Bugs Bunny was created when all toons had drops of sweat eject from the tops of their heads when they got nervous, and their eyelids were dark and shiny and opened and closed with a mechanical precision. A better image for some would be that mechanical owl in "Clash of the Titans" whose eyes blinked so loudly.

THE INNER EYELID

Any Trekkie will identify with the above title and its presence in Vulcans which allowed Spock to instinctively shield his optic nerve from the blinding rays of McCoy's experimental light bombardment which killed the creature within Spock. Its relevance here is that there's no better way to describe one of the tricks I discovered to keep my sight clear. It's related to the blinking problem, except that one applies this feeling with the eyes open. It actually feels like I'm lifting up another eyelid that sits directly on top of my eye, like lifting up a long skirt to reveal a white petticoat. It's a very calm feeling when it's achieved, and until I discovered the Seahorse and Zaphod techniques was one of my main tricks. I say "tricks" because one must trick the muscles into behaving with these images. The image for this one is, of course, Mr. Spock himself.

SEEING BEYOND

In Des Moines, the summer after my initial success, I discovered a trick more mental than muscular. It's important to not let the sight process get nervous, because it will panic and the muscles will contract severely (and bring my vision back to where it was when I needed glasses). To this end I tried to understand what it was that made my eyes go myopic in the first place. Bates talks about the effect that reading a lot has had on people's eyes in general, i.e. we have trained our eyes to see close in order to read, and many of us try to apply the muscle ratios needed to see very close to seeing far away, which doesn't work. The eyes have been shaped by nature (those of you who still don't believe in evolution will not like this. Sorry.) to see images far away. Seeing close is of secondary importance, in terms of survival. But the eye can adapt to either extreme. Force of habit will cause it to let one set of muscular ratios predominate, and since seeing far requires little or no muscular adjustment from a state of rest,

since the eye was built to see far, living a life where most sight is for distant objects, the muscles necessary to see really close will from disuse "forget" how to do it, like our toe muscles which only in persons without the ability to use hands are exercised enough to make the feet able to write with a pencil, though we all have the same sets of muscles. Conversely, prolonged use of the eye muscles for close work will tend to lock them into that pattern of performance, and one will with great difficulty if at all be able to relax them again to see far. (Computer screens are especially hard on eyes, because the screen image is not clear to start with, and the tendency to stare to see it clearly is encouraged.) Charles Darwin, in "The Descent of Man and Selection in Relation to Sex," makes the observation that "savages," as he calls them, meaning no disrespect, overwhelmingly see at a distance much better than Europeans. Of course. Savages don't read books all the time.

My eyes had gotten used to focusing in order to see close. I speculated that their tendency through learned unconscious habit to focus on close things, which entails crossing the eyes to varying degrees depending on proximity, probably was affecting my ability to see distant objects. In other words, my eyes were using see-close techniques for both near and far vision. At least, I thought, my eyes were thinking that objects were closer than they really were, and not understanding when they weren't getting a clear image. (To extend the Star Trek reference, in the first movie V-GER was thinking, "I have sent the creator the correct sequence. Why does the creator not respond?" Or in Robocop when he says "my targeting system is off." But he knew why. My eyes didn't.) I tried tricking my eyes into focusing for the proper distance by pretending the object in question was a little farther than it seemed. I got this idea while looking at the pattern of tiles in the Men's Room and trying to get the parallel lines to converge. This was a game I had played for many years, but now with my eyes more relaxed it had the effect of clearing up the image, specifically of removing the false second image caused by astigmatism, which according to Bates is simply another form of incorrect muscle adjustment. Just as all the eye muscles contracting will elongate the eyeball, so a few of them contracting will warp the ball just enough for the cornea to become uneven, which causes astigmatism and hence multiple images.

(Also, in the pamphlet that accompanied the "aerobic glasses" was an image of a stop sign that was split into two images, neither of which had all the parts. One is asked to bring the images together by looking as if at a distant object so that the stop sign becomes complete. One could do something similar on this page by trying to make the following two sets of letters converge in order to form a five-letter word (BATES):

X		X
B T S		A E
X		X
A E		B T S
X		X

Line up the X's and see if you can see all 5 letters in the words. It's tricky. [This document or at least the previous five lines should be printed in a monospaced typeface, 10 characters per inch.] The purpose of

this picture is to train the eyes to diverge in direction while looking at a close object, which helps relax them. It also causes the image in each eye to be equally important, forcing the weaker or less-used eye to pull its weight. This is probably the only part of that pamphlet of any value.)

With this trick I was for the first time able to hold my vision clear for long periods, that is longer than 20 seconds, without constantly shifting focus. I was able using this method to go through Lucia di Lammermoor's entire mad scene with sharp images, and that was in low light. My memory image for it is Zaphod Beeblebrox from the Douglas Adams "Hitchhiker" trilogy (now in five books), since he has two heads. When one looks past an object in the foreground, one will see two of the close object. When one looks at the foreground object, one sees two of the background object. I try to turn Zaphod's two heads into one by looking past them. Curious logic, I admit, but memory systems work best when they're quirky.

MUSCLE STRETCHING

As a matter of muscular hygiene it is good to keep the muscles stretched out -- ask any dancer or gymnast. The same applies to the eyes. In the morning, or whenever they're tired, it helps to stretch the eye muscles by moving them to their extremes-- right, left, up, down, and all directions in between. Many people have advocated this exercise; I saw it illustrated in a Charlie Brown cartoon when I was young. Most, I'm sure, never took the exercise seriously. My image for this is a Cylon warrior. Watch Battlestar Galactica, you'll understand why.

THE SIDE OF THE HEAD

At the same time I discovered the Seahorse muscle, I began to try consciously relax the muscles between the eyes and ears on the side of the head. These are not the same as the muscle I use to rock my skull forward, which is in front of my ear but attaches to my neck. These muscles are limited to the skull and extend up under the hair. The feeling I get when my sight is absolutely clear is one of utter freedom from tension, and thinking about these muscles often helps achieve that. My image for this is the famous Munch painting "The Scream," because of where the subject's hands are-- right on those muscles, or slightly below. Positional accuracy is not important.

CROSSING AND RELEASING

When I went to Paris to perform Ashley's opera at a festival there, I became more aware of a tendency for my eyes to want to cross when the image wasn't clear. For months I had resisted this urge, thinking it counterproductive. But now it occurred to me that maybe there was a tension problem there that I wasn't allowing to be resolved, so I let them cross. I had discovered early on that while practicing with the eye chart in the morning (and in this I combined palming with remembering black and shifting so that one eye was covered while the other tried to relax), the way each eye would go about relaxing would start

with it focusing really close (I didn't at first notice, since the other eye was covered, that this involved the covered eye crossing while the open one kept looking straight ahead), then gradually as I shifted it back and forth across the line of letters it would come into focus. (I also learned at this time that the eyes focus independently of each other, for when I would switch eyes the newly uncovered one rarely was seeing with the same degree of clarity that the one I had been practicing with was. This explained to me the difference between my eyes in my prescription. The right one had always measured up slightly weaker; actually it was just trying harder to see close. Now the right one sees clearly at least as often as the left one does.) Now, in Paris, I did the same thing without the other eye covered. They crossed, and I would shift my attention from what one eye was seeing to what the other was seeing, back and forth, and as they relaxed they would uncross and both eyes would be clearer. It's an interesting exercise to alternately disregard what the other eye is receiving. It made it clear that my eyes hardly ever see with equal clarity, and sometimes, depending on the circumstances of the light, even see colors differently. It also helps to make the more blurred eye clearer to instantly compare its image to the clear one. My memory object for this is the old Wilkinson blades sword logo, since they cross. In combination with the Zaphod technique, this can get the eyes clear very quickly.

THE FOREHEAD MUSCLES

This is my most recently codified relaxing tactic. After the Seahorse and side-of-the-head muscles had been employed for a while, I became aware of tension located in the area above my eyes, basically the forehead region. (I must stress that I was unaware of this tension until I'd been relaxing other muscles in the vicinity for some time. Indeed, this can be said for all the tensions I've released: In their turn, each was noticed only after others had been released, except of course the first one, which was released through suggestions from the Bates book as outlined above.) This forehead tension is quite subtle and I have been able to release it only through imagining the muscles to be more relaxed than they are, in effect willing them to release. It is difficult to effect this release without incurring or letting recur other tensions nearby, such as beneath the eyes. Still, on a recent road trip I enjoyed my highest percentage to date of absolute clarity with this concept, in conjunction with the Seahorse, shifting, remembering black and crossing & releasing. My image for this, I hope rather obviously, is the head of a Sperm whale with its enormous forehead area.

A WORD ON MY IMAGES

The images I have chosen to remind myself of the techniques herein described and the ones from the Bates book that I use that I have not described, have particular relevance in my life. I don't expect any of them to mean much to anyone else. If you choose to use mnemonic devices in your journey to better vision, please pick images of special meaning to you, for they are most easily remembered.

CONCLUSION

With my concepts and techniques kept readily accessible in my memory, I am able to successfully fight the incorrect muscular habits formed in my childhood and reinforced during the years I was dependent on refractive lenses. As time passes, it gets increasingly easier to keep my eyes relaxed and see clearly. I almost never wear glasses any more, and then only extremely briefly when I need to read a street sign while driving at night. The few times when I'm unable to adequately overcome eye tension, which are now no longer than half a minute and occur only after extended computer work or at the end of a long day, are a pittance to pay for the freedom from frames or contact lens chemicals and their accompanying expense. One of the greatest benefits is the ability to lean my head against something, be it a pillow or my beloved's breast, without any obstruction or worry about having to get up later and put contacts in a solution, and watch the TV or a sunset or the stars. Another great thing is that people look at me differently without the wall of lenses on my face. I didn't like contact lenses- they made my eyes tired and were too much trouble-so I went from a bespectacled aloof intellectual to a personable "normal" guy in the space of three weeks. I can play frisbee in the rain and go swimming with perfect clarity and no problems of fogging or losing a contact. I don't have to worry about where my glasses are. The list is very long.

Make no mistake, to unlearn bad vision habits is difficult and requires constant attention. It requires a strong will, immense patience and great determination, and mostly the desire for the freedom success brings. Everyone who wears lenses should be given the opportunity to apply Bates' techniques. All they have to lose is the freedom they are already denied by their dependence on their lenses. The gains are comparatively immeasurable. But millions are denied the mere possibility of awareness of these facts by the silence of those who, since they were taught otherwise or tried and failed, will not spread this knowledge. A recent National Geographic article on vision stated categorically without mentioning theories to the contrary, that science does not know the cause of myopia. Answering my letter to the editor, which pointed out Bates and his technique and its success in my case but which was not printed, the editor wrote me that, due to space considerations and expected interest to readers, many things, INCLUDING BATES' "THEORIES," had to be omitted! I wrote back asking what could possibly be of more interest to readers of an article on vision than the possible existence of an inexpensive way for a large percentage of lenswearers to rid themselves of their optical crutch. I have received no response to my second letter. And the Bates method was once again ignored. Bates' book has been in print over fifty years. It was sheer luck that I came across it at all. Once again, it's not a conspiracy. It is the inertia of ignorance and the inability of most people to think outside strictly conditioned pathways. I hope this little treatise will encourage others to give the Bates method or some variant a try and hopefully experience the joy I have.

Adam Klein
June 1993

UPDATE July 1994

Still not using glasses. Also, still not seeing clearly 100% of the time, but more often than before, with less work. I have been experimenting with where to focus the idea of relaxing, that is where in the eye area to simply "tell" the muscles to relax. This is a direct steal from my singing-learning process, and also from yoga. Try to feel tension, and then relax to get rid of it. The two spots I've been comparing are between the eyes and near their outer edges. I talked to a medical student in February, and he mentioned that there was a muscle that attaches obliquely to the eye, from the nose side on the bone to the temple side on the eye, and I wondered if that was the muscle which was making my eyes cross and not the ones on the outer part of the eye. After four months of trying to relax one and then the other region, it seems clear that for me it's better to relax the outer areas. They seem to be what makes my eyes cross, not the ones in between. So the "Geordi LaForge" area (described above as the "The Scream" image, but since then changed to Geordi, because of where his visor attaches to his head-- the actual area is slightly below where those clips seem to be, but close enough) is evidently one of the most important ones these days to concentrate on. Since settling on that area over the inner one, I can see clearer longer in much less light than before.

I should mention that my eyes never crossed before I started to figure out how to relax them, and they don't stay crossed. It's just until the muscles that are making them do that, which are very hard to feel, relax.

I have discovered Stereograms, random-dot and otherwise. If they're wide enough, that is, if one needs to look very close to parallel to see the image-- in other words, when the fusion dots approach 2.5 inches apart, they're very good for relaxing the eyes. Besides, they're too cool for words. I've even managed to make a stereoscopic desktop pattern for use with Wallpaper*, which itself, when using the 128x128 pixel patterns, is good for relaxing. A large monitor helps.

Don't Try This at Home or How I Risked My Life for Eye Research

By Rich McCollim

The familiar concept that myopic eyes tend to have greater axial length suggested an idea: Myopic eyes are long, so why fool around. Why not just shorten them? A search of the literature indicated that apparently no one had ever suggested this, let alone made the attempt. I quickly rejected any mechanical means, such as some sort of calipers to compress the eyeball longitudinally. The obvious answer was centrifugal force, applied so as to push the eyeball from the front. The subject would sit in a chair mounted on a revolving base, facing inward toward the center of rotation. As the speed is increased, so does the centrifugal force exerted on the eyeball. Not only would this shorten the eyeball, it would have the serendipitous effect of flattening the cornea, an additional advantage.

I made a rough sketch of the device and found a rundown machine shop in Tijuana whose owner gave me a good price to produce the various parts, which I then smuggled into the U.S. to San Diego (although one may bring in several hundred dollars worth of goods duty-free, duties are supposed to be paid for any item that is custom-made). I bought a rather expensive variable-speed direct-current electric motor and assembled the device in a rented garage. The chair in which the subject sat was of welded steel, firmly braced with strong steel aircraft cable. I grandly christened my device the "Optifuge", with which I was going to make ophthalmological history.

The first trials were inconclusive because I kept the rotational speed very low until I got used to the very unpleasant effects of vertigo and nausea. I had made numerous calculations to determine what speed would produce a given number of g's. Two g's (which meant that my body weight became twice that of normal) was fairly uncomfortable but bearable. I had originally thought only about exerting g forces on the eyes, forgetting for the moment their effect on the entire body. I was able to gradually increase the speed. Spinning round and round in a circle, with a diameter of about six feet, everything was a complete blur even at lower speeds of 20-30 rpm. I was eventually able to increase the speed to over 100 rpm, equal to 5 g's, which was so painful that I could do this for only one or two minutes before having to shut down. At five g's my normal body weight of 185 pounds was equal to 925 pounds. The centrifugal force was so great that it took all my strength to move my arm from my chest out some eight inches in order to reach the shutoff switch. This switch was controlled by a nylon cord that hung down from the ceiling directly in the center of rotation, so that it could be reached no matter where I was within the circle of rotation.

I also had a secondary shut-off switch actuated by a spring-driven timer, which I would usually set to

turn of the Optifuge automatically in case I was unable to do it manually.

I used this device almost daily for some six months, and although I did note some changes in visual acuity, which I thought were due to either axial shortening or corneal flattening, or, more likely, both, I eventually concluded that the idea was a failure. And even if it had succeeded in curing or reducing myopia, few people would be willing to do this.

However, before I terminated the project I had one life-threatening experience. Since I usually used the manual shut-off switch to stop the rotation, I didn't pay much attention to the backup switch. It was a cheap spring-loaded device that I had bought in a hardware store. The time setting was done by a pointer that was rotated clockwise around a dial until the time was set--5 minutes, 10 minutes, etc. As the dial was turned, the spring tightened. The greater the time limit set, the tighter the spring wound. However, I noticed (but didn't think much about it at the time) that if I set the timer to only one minute or so, the spring was barely tightened and sometimes didn't have enough tension to fully turn the point back to zero, which would turn off the switch.

One day I decided to go for the maximum number of g's, and set the device to wind up to 120 rpm. In about 20 seconds I decided I couldn't take it anymore and reached for the cord to shut down. Unfortunately, the high rotational speed produced strong air currents that swung the cord, even though weighted at the end with a piece of metal, away from the center. On my second attempt at grabbing it I instead hit it with my hand and knocked it upward where it got hooked on one of the wooden roof beams, totally out of reach! This scared the hell out of me! The g forces were so painful that I didn't think I could last more than a minute or two more. Also, because blood is pushed toward the occipital area of the brain and of course starves the frontal area, I had the feeling that I was going to black out. If I had managed to get out of the chair (very unlikely), I would have been thrown against the wall doing about 40 miles per hour. Because I had set the timer for only about two minutes, I immediately remembered how it had failed a few times in the past when set for short time periods. After what seemed like forever, I heard the most wonderful sound, a faint click as it switched off and the electric motor began slowing and then came to a gradual stop. Whew!

(Actually, this happened fairly early in the experiment, before I had found out all I wanted to know. Since I wanted to continue a little more, I had a machine shop build a stainless steel cylinder, about 10 feet high, which was bolted onto the base of the machine. The device now weighed more than a ton. I now had a futuristic rocket-appearing device that looked more professional. Now I would enter through a door in the side, and that made me feel more secure, along with the fact that the switch cutoff cord hung down through a small hole in the roof of the device, protected from any air currents.)

A Case of Artificially-Induced High Myopia and Implications for the Mechanism of Accommodation

By Rich McCollim

Is it possible that the almost universally accepted theory of accommodation is wrong? The following is an account of an experiment which produced a very surprising and unexpected result which calls into question current theory.

The standard explanation of myopia is that in the myopic eye, the light rays passing through the crystalline lens come to a focus in front of the retina, and that this is usually caused by the eyeball being too long. The result is blurred vision for objects at a distance. I decided to test this theory by compressing the eyeball, with the idea that this would lengthen it longitudinally (by compressing it approximately in the middle). In other words, the object of the experiment was to deliberately produce myopia. My method for compressing the eyeball is explained in Appendix A.

Since I could hardly ask someone to be the subject of an experiment designed to worsen his vision, the subject of the experiment necessarily had to myself.

I reasoned that if I did succeed in lengthening the eyeball, then my vision for distance would become blurred, i.e. I would become myopic. However, because I was already myopic (O.D. -7.75-1.25; O.S. -5.50 -1.50), the object of the experiment would be to increase the degree of myopia.

I began to wear the device, strapped to my head, for three to four hours per day (used for distance vision only) and periodically checked my visual acuity for any sign of increased blur. After several weeks of this regimen I noted the first definite sign of change--but precisely the OPPOSITE of what I had predicted: my visual acuity for distance had definitely increased! In fact, with continual wearing of the device I eventually reached the point that my visual acuity (which for many years had been myopic, with uncorrected acuity at around 20/) was in the range of 20/30 - 20/40. To a lifelong myope this seemed almost the equivalent of perfectly clear vision. At the time I was 35 years old and had been wearing corrective lenses, of gradually increased power, since the age of six.

It seemed obvious that this remarkable change in acuity had been caused by something to do with the experiment, but by what means? Another puzzling factor, was that even with my near-sharp acuity, blur was still present. The subjective experience of this effect was as if two photographic transparencies, one blurred and one sharp, were superimposed one on the other. It should be made clear that this was monocular, and approximately to the same degree in each eye. The crucial question was, how had squeezing the eye produced dual vision? There are a few reports in the literature on double focal points resulting from cataracts, but this case was clearly different.

I hypothesized that the creation of dual vision was the result of contraction of the superior oblique muscles which had exerted pressure on the globe, which was transmitted through the sclera to the vitreous, forcing the vitreous against the back of the lens and flattening its periphery. Rays passing through this outer region of the lens came to a focus at a point very close to the retina, which produced the secondary image (clear vision), while the rays passing through the axial (central) region of the lens came to a focus in front of the retina, which produced the primary image, which was severely blurred. Moreover, this blur was of much greater degree than the blur of my original myopia. In other words, I had increased the degree of my myopia by some 5 diopters in less than two months! My original lenses had become totally inadequate, and I required a new prescription: O.D. -11.75 -2.25; O.S. .9.00 -2.00.

The Persistence of Accommodation and the Etiology of Myopia

The creation of a dual mode of vision was quite remarkable, but another intriguing finding was that the dual vision persisted even after the experiment was stopped. I reasoned that the lens had become permanently distorted as a result of vitreous pressure. Further, despite the nearly sharp acuity, this was present in only one of the two modes of vision, and that in the other I had become much more myopic. (This, of course, quickly dampened my initial enthusiasm that I had discovered a cure for myopia). The most significant point, however, is that these changes in acuity came principally not from elongation of the globe, but rather from changes in the shape of the crystalline lens. So, the object of the experiment was achieved--increased myopia; in fact my visual acuity with my original corrective lenses had deteriorated drastically (around 5 diopters) in less than two months. I eventually concluded that what I had was a case of spherical aberration carried to an extreme degree. (See Spherical Aberration in Appendix B).

If it were true that the cause of my dual vision was spherical aberration resulting from deformation of the lens, then the lens had become accommodated, since accommodation is always accompanied by spherical aberration, and vice versa. Therefore, the persistence of dual vision indicated that the accommodation also persisted. In other words, I had increased my myopia remarkably, but as a side effect had created a second mode of vision close to emmetropic.

Implications

I concluded that the bizarre results of this experiment had major implications for the conventional wisdom about eye mechanisms in several areas. I could be cautious here, but why be reticent? ii 1. The Helmholtz-Fincham theory of accommodation is wrong. Accommodation is actuated by contraction of the ciliary muscle, true, but probably not by relaxation of the zonule so much as pulling the vitreous against the posterior surface of the lens.

2. The principal cause of myopia resides in the lens, and to a lesser degree in axial length.

3. The argument that myopic lenses are not accommodated because they tend to be thin

is wrong. This could be explained by long-term compression, which produces a permanently accommodated lens in which only the periphery is flattened.

4. The extraocular muscles can cause the lens to accommodate.

Obviously, these statements directly contradict much of the conventional knowledge about eye mechanisms, for which there is a mountain of evidence. Below I will attempt to answer.

The Zonule Relaxation Theory of Accommodation

If the dual vision observed was caused by vitreous pressure, then the Helmholtz-Fincham theory of accommodation can not be correct. Briefly, the Helmholtz-Fincham theory states that the lens accommodates by means of relaxation of the zonular fibers. "Accommodation results from decreased tension: the driving force--the motor--is the lens capsule. The decreased tension theory is attributed to Helmholtz. Considering the evidence, there is little reason to still call it a theory. Its only serious rival, proposed by Tscherning at the turn of the century, just survives by textbook repetition." (5, p. 87)

The hypothesis of vitreous pressure comes up against three exceptionally strong arguments. The conventional view is that:

- 1) The vitreous is unimportant in accommodation. This is proven by experiments in which accommodation occurs even without the presence of the vitreous in cases of vitrectomized eyes.
- 2) When the lens is freed from zonular tension, it assumes a more spherical shape, i.e. increases its power.
- 3) The zonular fibers relax during accommodation. When accommodation is observed in an eye in which the iris is absent, thereby exposing the zonules to view, they are clearly seen to relax their tension.

My answers to these objections are as follows:

- 1) That the vitreous is not required for the eye to accommodate. Almost all eye researchers support this view. For example, Fisher states that "The vitreous plays a negligible role during accommodation in modifying the position or shape of the lens." Burian and Allen state that "...our observations on the periphery of the vitreous surface strongly suggest that the vitreous body, far from pressing on the periphery of the lens, was actually under reduced tension during accommodation." (8)

However, a few researchers contradict this view. Araki reported that in experiments on pig, dog and cat eyes, "...it is suggested that tension of the ciliary muscle/zonules stretching from the posterior surface of the lens was increased by forward movement of the ciliary body and consequently it resulted in pressure to the posterior peripheral (my emphasis) part of the lens...the increase in pressure of the vitreous body due to contraction of the accommodative muscle is considered to be the most important factor for the transformation of the lens." (10)

Suzuki performed an experiment in which he injected radiopaque material into

the vitreous of a cat's eye, which during accommodation moved in a direction indicating that the vitreous was forced against the back of the lens and also somewhat toward the posterior pole of the lens." (11)

An experiment by Koke produced a similar result. He injected cat eyes with radiopaque material and took X-rays during miosis and mydriasis, which showed that during accommodation the vitreous moved toward the lens and inward toward the optic axis. (12)

The experiment that is most closely related to mine, because it involved external pressure on the globe, is that of von Pflugk. He cut windows in the equatorial region of bovine eyes and injected a drop of dye into the anterior vitreous, midway between the ciliary body and the posterior pole of the lens. Pressing against the ciliary body from the outside in a radial direction made the dye move toward the lens capsule. (13)

2. The second objection to the vitreous/lens hypothesis is undoubtedly the strongest of all: the demonstration that when freed from the tension of the zonule, the lens assumes a more spherical form.

It is probable that the experiments of Fincham, more than any other factor, tilted opinion away from Tscherning's theory and towards that of von Helmholtz. In what is undoubtedly the demonstration that clinched the case for zonular relaxation once and for all, he showed conclusively that without the tension of the zonule, the lens becomes more spherical. An eye was made to accommodate for distance viewing by the instillation of atropine and then removed from the orbit and pointed upward after dissection of the cornea and iris. The profile of the lens can then be photographed, and in this condition it demonstrates the characteristic shape of the lens when the eye is looking at a distance. However, when the fibers of the zonule are severed all around by the sharp edge of a knife, the curvature of the anterior surface increases markedly and "assumes the shape that it has under maximum accommodation," i.e. the lens becomes thicker, as is clearly seen in the photographs taken by Fincham.

This appears to be an unassailable argument. To recapitulate: when the zonules that hold the lens in place are cut, the lens immediately becomes more spherical, which obviously increases its power, a highly convincing demonstration.

To counter this argument requires rejection, not of Fincham's observation (the photographic evidence is too strong for that) but of his interpretation. When the zonules were cut and the lens became more spherical, he ASSUMED that the consequent change in the shape of the lens was the same as that which occurs in accommodation. Could this be a non sequitur? I believe that it is at least possible.

It is not inconceivable that the shape he observed was not the shape that occurs in accommodation but merely looked like it. It is possible that the lens could assume a more spherical shape under two different conditions: 1) When released from the tension of the zonule and 2) When molded by vitreous pressure, with only the latter being true accommodation.

3. The third objection is based on the well-documented evidence that when the lens accommodates, the zonular fibers relax their tension. The vitreous/lens hypothesis, however, requires that there be some means to counteract the vitreous pressure. If the lens is pushed forward by the vitreous, what could hold the lens in its place? Obviously, the zonular fibers could not fulfill this function if they are relaxed.

Although most of the standard textbooks on ophthalmology state simply that in accommodation the zonular fibers relax their tension, this is not the whole story. Several investigators have shown that there are TWO sets of fibers, and that while the anterior fibers relax in accommodation, the posterior fibers either remain tensed or increase their tension. I suspect that acceptance of the relaxation theory was due in part to the fact that the anterior fibers, being the most easily observed, were the first to be discovered and studied.

Evidence for the existence of two sets of zonular fibers has been reported by several investigators. According to Suzuki, "during accommodation the posterior valley became swollen toward the inner direction of the eyeball. This could account for the relaxation of the zonules attached to the anterior surface of the ciliary muscle.

"During more advanced accommodation, the anterior valley sank toward the outer direction of the eyeball. This could account for the **contraction** of the zonules attached to the posterior surface of the lens (*italics added*). (11)

An experiment by Araki showed that "electric recordings of the changes in tension of the ciliary zonules suggested relaxation of the zonules which was (sic) stretched to the anterior surface of the lens and on the contrary, increased tension of that stretching to the posterior surfa (cat and dog eyes). (10)

The Iris

Although it is possible that tension of the posterior zonular fibers might be sufficient to withstand the pressure of the vitreous against the lens, I find this unconvincing.

What other mechanism could hold the lens in place? An obvious candidate would be the iris, if it weren't for the fact that more than a hundred years ago von Graefe showed that the lens can accommodate perfectly well even when the iris is not present. The anterior surface of the lens is slightly conoidal, and earlier investigators proposed that this was caused by constriction by the iris, the lens being molded by being forced through the opening of the pupil.

Apparently, von Graefe's demonstration was all that was needed to disprove the iris hypothesis, yet it would seem unwise to base such an important conclusion on a single case. Further-more, as I suggested above, when the lens is released from traction, the more spherical form that it assumes may not be true accommodation. If this is correct, and if the full amplitude of accommodation seen by von Graefe was not true accommodation, then his conclusion that the iris is not required for accommodation may be wrong.

It is highly improbable that with the vast amount of research done on the iris, such an important function as counterpressure on the lens could remain

undetected. Yet a number of reports do suggest an iris/lens connection. And it is interesting that the researchers themselves seem to be surprised by their findings. Lowe reported that "During examination of a large series of eyes that had pupils dilated after peripheral iridectomy...I was struck by the marked curvature of the anterior lens surface within the enlarged pupil. +The lens frequently appeared as though it were herniating through the enlarged pupil, with the pupillary margin of the iris seeming to grip the lens." (15)

Jampel and Mindel, in a report on stimulation of the oculomotor nucleus in monkeys, observed changes "... characterized by a conspicuous forward bulging of the pupillary or central portion of the iris which produced a marked convexity of the iris diaphragm and a marked increase in the depth of the anterior chamber...On observation of the eye from the side during iris-bulge, the central portion of the lens appeared to become conoidal and to move forward into the anterior chamber." (17)

Although it is generally believed that the changes in lens shape in accommodation occur principally in the anterior surface of the lens, the hypothesis proposed here suggests that the posterior surface might undergo equal or greater changes due to its direct contact with the vitreous.

In the rhesus monkey there is a similar mechanism involving the iris and the sphincter muscle, although it is not clear which of these is of greater importance in molding the lens.

Burian and Allen reported that "The most remarkable change was seen in the middle one-third of the body of the iris. This part of the iris bowed backward during active accommodation, forming a deep hollow, and returned to its normal position when the eye was relaxed."

And Suzuki states that "Concerning the iris, its silhouette was a slightly curved line, being convex anteriorly in the form of a physiological 'iris bombe'. On stimulation, the iris showed a peculiar change. That is, besides the change of the contraction of the pupil, the iris was bent reversely to the posterior chamber, so that the central half of the iris was held in contact with the anterior surface of the lens and the iris-lens apposition became tighter over a much larger area."

All four of these reports describe the iris as being pressed against the lens, and two of them note that the conoid form of the lens appears to be the result of bulging through the pupil. Could the iris play a major role in accommodation after all? This may appear too speculative to be taken seriously,, yet the iris/lens mechanism is a well-documented fact in certain birds and mammals. According to Walls, "The avian iris is always of material assistance during accommodation in holding back the lens against which it presses, and in inhibiting the peripheral part of the anterior surface of the lens from bulging, thus concentrating the change-of-curvature in the part of the surface opposite the pupil." (18)

Posterior and interior lens changes

The conventional wisdom that the principal changes occur in the anterior lens was challenged by Patnaik, who wrote that "...the often stated and commonly

accepted statement, that it is the anterior lens surface which moves forward while the posterior surface remains stationary and that it is only the anterior surface which changes its curvature during accommodation seems not to be correct.

"Our observations strongly indicate that during accommodation the increase in the thickness of the anterior cortex is minimal, and that the change in the posterior cortex is greater, and that in the nuclear thickness change is greatest." This last may be especially significant because it raises the possibility that the principal source of increased lens power in myopes could be the nucleus.

Young also commented on the importance of the posterior surface: "The pressure changes in the vitreous chamber may also play a role in the process of accommodation, since the back lens surface could be molded by the increase in pressure more effectively than the front lens surface. Unpublished phakometric studies now indicate that the back lens surface contributes almost twice as much to the total vergence of light and is second only to the cornea in its refractive power. The attachment of the hyaloid membrane to the back lens surface may play a major role in the development of the greater lens power of the back lens surface. There is some evidence from children (sic) phakometry that the back lens may have several curvatures rather than the simple, monotonic curve of the front lens surface."

The Lens Capsule

When Helmholtz first proposed his relaxation theory of accommodation, it was criticized on the ground that relaxation of the zonule failed to explain how the anterior central region of the lens assumes a conoidal shape. Tscherning claimed that this could only be produced by pressure from the vitreous, which he believed molded the softer cortex of the lens around the harder nucleus. Fincham thought he found an answer in evidence that the thickness of the lens capsule varies, and he believed that these minute differences in thickness were sufficient to impose a conoidal shape on the anterior surface of the lens (14).

Although it is conceivable that the capsule could mold the lens to a slight degree in this manner, the evidence from my own experiment indicates that this explanation is insufficient. Because the degree of spherical aberration was so extreme, which indicated extreme flattening of the periphery of the lens, it is difficult to believe that it could have been produced by such minute differences in capsule thickness. In fact, the contrary could be argued just as persuasively: that the differences in capsule thickness could be the RESULT of pressure on the lens. The thin segment of the capsule in the anterior axial area could be caused by stretching of the capsule, while the thin posterior segment could be caused by the vitreous squeezing the capsule against the lens.

The Extraocular Muscle Hypothesis

The hypothesis that the extraocular muscles play a role in the causation of myopia is certainly not new. It has been suggested by numerous investigators over the years. A major difference, however, is that in none of these

hypotheses has it been proposed that they have any effect on the lens. All are limited to the concept of elongation of the globe, usually through elevation of the intraocular pressure.

The case is similar with regard to the numerous hypotheses that propose contraction of the ciliary muscle as a cause of myopia. They all postulate that such contraction elongates the globe, and do not suggest any effect on the lens.

The Persistence of Accommodation and the Etiology of Myopia

A significant feature of the experiment was the amount of time in which the lens was subjected to pressure and, I believe, accommodation. An eye whose lens remains accommodated will show blurred vision for distance gaze. But the lens is not supposed to remain accommodated when the stimulus for accommodation is removed. According to orthodox theory, accommodation is maintained only as long as the gaze is directed at a near object. When the gaze is shifted to a distant object, the lens reverts almost immediately to the unaccommodated form required for distance vision. The consensus of opinion is that these accommodative changes take about one second. I believe that this view is too restrictive, probably a result of too much reliance on laboratory studies that deal only with momentary accommodation, and that there is a crucial difference between momentary and repeated prolonged accommodation.

The persistence of dual vision in my own case, as well as the findings of a number of investigators on the slowness of lens changes, leads to the conclusion that the longer a lens is maintained in a particular form, the longer it takes to return to its original form when released. Further, with high degrees of deformation the lens does not return entirely to its original form. In my case, the sharp image persisted for more than four years before it gradually began to disappear. I assume that this was due to a gradual decrease in the degree of flattening of the periphery when the pressure was removed. Since the blurred component of the image remained largely unchanged, apparently this was because the central region of the lens changed very little.

On the question of the slowness of lens changes, I am not alone. Lancaster states that "...if the accommodation is maintained a few minutes at the maximum, the near point does get nearer and the eye may become accommodated 20% to 30% or more, nearer than at the first. If the near point at the start was 6 D. it may become 7, 8, or 9 D. This...is due to the viscosity of the lens substance. An immediate rapid (about one second) change takes place when the lens adjusts itself for a near object, but if a maximum effort of accommodation continues to be made, the lens slowly (5 to 10 minutes) goes on changing its shape and becoming more strongly refractive.

"Commonly, when the eye, after such an intense effort of accommodation, is shifted to a distant object, although the ciliary muscle may promptly relax, it takes time (a few seconds to a few minutes depending on how long the near effort was continued) for the lens to regain its normal shape adapted to a distance. This is due to the viscosity which makes a change in the shape slow"

Other investigators have also demonstrated the slowness of lens changes.

According to Kikkawa and Sato, "Application of an external force to the lens caused a rapid deformation followed by a second phase of slow deformation. On removal of the force, a rapid partial reversal of the deformation occurred and was followed by a gradual restoration; complete recovery was not achieved.

Kabe reported a similar result from his investigations. He showed that when accommodation is increasing, the change in the apparent curvature of the anterior surface of the lens is slow and continuous, but when accommodation is decreasing, there is a prompt, followed by a slow phase (21).

The idea that myopia could be the result of increased lens power has always been countered by a very strong argument. If in myopic eyes the lenses are permanently accommodated, they would tend to be thicker than the lenses of emmetropes. Not only is this not true, but in general, myopic eyes tend to have even thinner lenses than emmetropes. As far as myopia is concerned, there is a clear consensus of opinion as to the importance of the lens: It ranks very low.

"Three variables, then, the axial length, the shape of the cornea, and the power of the crystalline lens, exert the greatest effect upon refraction. There is good agreement among authors as to the relative influence which each of these exerts, the axial length being the greatest, followed by the cornea and lens in that order. There are minor disagreements among investigators as to the relative importance of the least of these three elements, the crystalline lens: Van Alphen's work suggests perhaps the lowest estimate of the importance of the lens. However, all investigators arrive at the same order of importance, and at relative values not too different from those obtained by others".

Sorsby seemed to be puzzled by the existence of thin lenses in myopes and tried to find a way out of the difficulty by speculating about the tension of the zonule. He stated that, "Obviously, a large fairly spherical eye will have not only a long anteroposterior axis but also a flatter cornea. Flattening of the lens in a large eye is more difficult to understand, but a more marked tension on the suspensory ligaments may be a possible factor."

The barrier to a resolution of this contradiction seems to be the belief that a thin lens can not be an accommodated lens. But if the slowness of lens changes is correct, and there seems to be no dispute about this, then in myopes the lens must be accommodated. Consider the case of a myope with a history of nearwork, e.g. with hour after hour of reading over months and years. It could very well be that with repeated periods of prolonged accommodation the lens, with its slow reaction time, would never return completely to the unaccommodated state.

The conventional wisdom is that the lenses of myopes are not only not of the same power as emmetropes, but are of even lower power. How can this be? It would appear that eye research is so compartmentalized that two such contradictory facts--thin lenses in myopes and the slowness of lens changes--can go unnoticed and unresolved.

The possibility that a lens subjected to frequent prolonged accommodation for months and years may not have the same shape as a lens that is ad for months

and years may not have the same shape as a lens that is accommodated momentarily has apparently not been considered.

The hypothesis of vitreous pressure suggests that such prolonged pressure might produce a lens with a flattened periphery but with a high degree of curvature in the axial region, i.e. a lens that is thin yet accommodated. I have found only one reference in the literature that even indirectly supports this hypothesis. In a study of accommodation, Otsuka stated that "the thicker the lens became during accommodation, the thinner the lens became annually." This is intriguing, but unfortunately he did not elaborate.

It may be that a single factor, external pressure on the globe, produces two separate effects, in opposite directions: anteriorly it accommodates the lens, and posteriorly it elongates the globe. I believe that one consequence of this dual effect is that axial elongation has masked the role of the lens. With such a logical and easily demonstrated explanation available, there has been little incentive to look for an additional factor, and thus the lens has been practically ignored.

The indications that external pressure had produced accommodation by forcing the vitreous against the lens suggests the possibility that the vitreous plays a part in normal accommodation, i.e. that the experiment mimicked what happens in normal accommodation. It is possible that in normal accommodation, contraction of the ciliary muscle pulls the vitreous forward against the lens (as suggested by Cramer in 1851, and later by Tscherning), whereas in this experiment the vitreous was pushed forward by external pressure exerted on the globe.

Theory versus Observation

Curiously, there is a case of photographic evidence that the lens becomes thinner with accommodation, even momentary accommodation. This appears in a paper by Burian and Allen which shows photographs of the lens during three stages: 1) Relaxation of accommodation; 2) Active accommodation; and 3) Active accommodation (apparently further). However, instead of showing that the lens thickens with accommodation, it shows precisely the opposite. In each photograph it can be clearly seen that the lens becomes progressively thinner, at least in the peripheral area.

These photographs are reproduced in Duke-Elder's System of Ophthalmology (25, p. 163--possibly different pages in other editions) and in a more recent work by the late David Michaels, Visual Optics and Refraction. Nevertheless, except for noting the flatness of the posterior surface of the lens, none of these authors comment on the striking fact that the lens clearly becomes thinner as it accommodates. In fact, in the text preceding the photographs, Duke-Elder states: "All are agreed that the lens increases in thickness during accommodation" (!!). It seems that theory is more potent than direct observation.

An additional note on this photograph: Burian and Allen state that "our observations on the periphery of the vitreous surface strongly suggested that the vitreous body, far from pressing upon the periphery of the lens, was actually under reduced tension during accommodation." They believe that the

evidence for this is the bowing back of the vitreous, which they believe creates "an optically empty space in front of the vitreous." They fail to explain how this "optically empty space" could occur. A possible explanation is that this space, apparently the canal of Petit (the space between the zonule and the vitreous) has expanded from an inflow of aqueous under pressure. Johnson demonstrated such an inflow by the use of dyes, and he believed that accommodation was actuated by hydraulic pressure exerted around the periphery of the lens (9). Duke-Elder dismissed this as a "bizarre hydraulic theory," but the opening and closing of the trabecular meshwork by the action of the ciliary muscle does suggest a hydraulic component of accommodation.

Lens Changes Hidden

If significant lens changes do occur in the posterior surface of the lens, this would be one more example of how the clues to lens involvement in myopia are hidden.

Consider the case of a myope who undergoes a routine eye examination. If he has a moderate degree of myopia, the posterior surface of the lens could be flattened just enough to have created a second focal point. However, the examiner would never discover this for two reasons: He will probably not look for something whose existence he is unaware of; and because the second focal point would not reach all the way to the retina, no clear secondary image is formed. Only with a particular lens power which would push the secondary focal point to the retina would a clear secondary image be formed.

Additional Secondary Images

In order to simplify this discussion, I have limited it to the primary and secondary focal points and their images. Actually, however, testing of myopes with different lens powers reveals that there are often other images, fainter and more difficult to detect, which indicate the presence of other focal points situated between the primary and secondary focal points. The origin of these could be the various isoindicial surfaces within the lens. Some high myopes, when tested with various lens powers, describe not a smooth, diffuse blur, but rather several superimposed blurred images.

Although I didn't appreciate it at the time, it was fortunate that the first subject for the experiment was myself. What if I had found a willing emmetrope, or a subject with only a small degree of myopia? The outcome would probably be very different. The experiment would probably produced a small degree of myopia, partly from axial elongation and partly from lens changes (just as I believe occurs in normal myopia).

The significant point, however, is that I would never have suspected the lens, but would have attributed the myopia to axial elongation alone. Because I was a myope of fairly high degree, I believe that flattening of the periphery of the lens was fairly well advanced, so that the secondary focal point was already located very close to the retina. It then required very little additional flattening to push all the way, or very close to, the retina, at which time I became aware of the secondary image.

A laymen who reads textbooks on ophthalmology can easily get the impression of a solid edifice of knowledge built on firm foundations. Yet at least one researcher, Ludlam, suggests that some of the most basic facts about the eye are based on faulty data and should be re-evaluated. These include invalid mathematical assumptions, mixed sampling, inadequate experimental technique, and oversimplified models of the refractive system, some of these dating from the nineteenth century.

"Nevertheless, the analyses and conclusions drawn from such studies can be no better than either the methods of acquisition of the basic data or the validity of the assumptions underlying the mathematical formulation of the ocular model.

"It is well to note that in all of these studies the model of the ocular system utilized has consisted of:

1. Spherical refracting surfaces, causing a systematic under-estimation of the paraxial refracting power of each surface. 5. A homogeneous monoindicial lens. This places a high order of importance on the accuracy and precision of the measures of curvature of both the anterior and posterior surfaces of the lens and concomitantly increases the potential effects of spherical assumption.

" In addition, in none of these studies have all the refractive components of any given eye been measured. There has always been at least one component whose value was calculated from the other measured elements, so that the measurement errors would all tend to accumulate in the non-measured element. Since the measurement errors have not always been stated with sufficient clarity to enable the effects of these errors to be asses, the probability exists that measurement errors have contributed substantially to spurious correlations of measured and calculated elements, as for example between the lens and axial length." (29)

To say that long-standing theories are not easily overturned is to state the obvious. As Kuhn put it, "...few scientists will easily be persuaded to adopt a viewpoint that again opens to question many problems that had previously been solved" (30, p. 169). Ophthalmology is no exception, and scattered reports in the literature that cast doubt on the conventional wisdom, for just one example, a case described by Luedde (31), are simply ignored.

How Not to Cure Myopia

The lens/vitreous hypothesis provides an explanation for the failure of two therapeutic measures aimed at preventing or slowing the progress of myopia: the use of cycloplegics, and base-in prisms. In the case of cycloplegics, they relax the ciliary muscle for only a few hours at a time, while the lens requires many months for a significant reduction in the degree of accommodation. More importantly, in all these regimens the subjects are permitted to continue doing nearwork, so that accommodation could still have been maintained largely by vitreous pressure alone.

The use of base-in prisms to prevent convergence, and consequently accommodation has, I believe, failed for an unsuspected reason: the optical distortion inherent in such prisms. I used base-in prisms extensively in

various experiments aimed at reducing accommodation and was surprised to find that in some cases the degree of myopia increase. Strong base-in prisms produce considerable distortion, and a possible explanation is that in trying to fuse the distorted images, the eyes were forced to incyclorotate in antagonism to each other, and this in turn required the superior oblique muscles to maintain contraction as long as the image was fused, thereby exerting pressure on the globe and maintaining accommodation.

Scientific Error

It is highly unlikely that such well-established concepts as the theory of accommodation and the role of the crystalline lens could be wrong. The relaxation theory is extremely well documented and for more than forty years has been considered the only acceptable explanation of how the eye accommodates for near vision. The possibility that many researchers in many different countries could be wrong about such a basic theory will not be taken seriously.

Nevertheless, there have been a few cases of major reversals of scientific opinion. The case of nervous system plasticity provides a good example. For more than fifty years it was universally believed, and confirmed by hundreds of experiments by reputable scientists, the plasticity of the central nervous system allowed any muscle nerve to reconnected to any other muscle and, with training, achieve full restoration of function. it is now known that this is not true.

According to R.W. Sperry, "During the past 15 years, however, scientific and medical opinion has undergone a major shift, amounting to an almost complete about-face ... The evidence for this view, which comes from new experiments and exacting clinical observations, is so persuasive that it is difficult to understand how the opposite view could have prevailed for so long. It appears that most of the earlier reports of the high functional plasticity of the nervous system will go down in the record as unfortunate examples of how an erroneous medical or scientific opinion, once implanted can snowball until it biases experimental observations and curshes dissenting opinions...Hundreds of experiments seemed to support the now-discounted opinion..." (28).

CONCLUSION

1. An experiment in long-term compression of the globe of the eye created monocular diplopia, seen as two separate images superimposed, one on the other.
2. It is hypothesized that the cause of this effect was the spherical aberration of the crystalline lens resulting from pressure of the superior oblique muscles transmitted through the sclera, which forced the vitreous forward, pressing it against the posterior surface of the lens.
3. This suggests a role of the vitreous in normal accommodation, i.e. that ciliary contraction pulls the vitreous forward to mold the lens.
4. This vitreous-mediated accommodation may be enhanced by additional compression from the vitreous from an external source, the action of the extraocular muscles.

5. The extremely slow changes in lens shape strongly implicate nearwork in the etiology of myopia. Because of the slowness of recovery from accommodation, long periods of accommodation with insufficient intervals of rest result in a lens that becomes permanently accommodated. The accommodated state of the lens may be additionally enhanced by the action of the extraocular muscles in nearwork, particularly reading.

6. The argument that myopic lenses are not accommodated because they tend to be thin could be explained by long-term compression. This could produce an accommodated lens with either a flattened periphery and convex axial region, or a thin lens with accommodative changes in the nucleus.

It would be curious if, after the tremendous amount of work and speculation on the causes of myopia, the answer turned out to a simple one, the kind of answer that might be given by a layman applying superficial logic. Assume that this hypothetical layman hears a brief explanation of the mechanism of accommodation: that when looking at distant objects the lens becomes somewhat flat, but that in order to see near objects clearly, it becomes more spherical; and if it were able to retain its spherical form while looking at distant objects, they would be seen as blurred since the eye is adjusted for near vision. Then he is given a brief description of myopia, that the myope sees near objects clearly, but distant objects are seen as blurred. He is further told that the longer the eye is focused on a near object, the longer it takes to change its shape. It would be not at all surprising if he made the logical connection and said, "I get it. The eye adjusted for near vision and then sort of got stuck so it can't re-adjust for distant vision."

Although the lens/vitreous hypotheses doesn't resolve all problems, I believe it resolves some, and anyway, as Kuhn Points out, "no paradigm ever solves all the problems it defines and since no two paradigms leave all the same problems unsolved, paradigm debates always involve the question: Which problems is it more significant to have solved?" (30, p. 110).

It is interesting to consider the extent to which a mistaken theory is a barrier to solution of a problem, and how a new point of view can open up previously unconsidered possibilities. These possibilities could include not only finally determining the etiology of myopia, but could include prevention, or even cure.

The pessimistic view was expressed by Donders over a hundred years ago: "The more our knowledge of the basis of this anomaly has been established, the more certainly does any expectation (of a cure) appear to be destroyed, even with respect to the future" (32, p. 415). Today, probably most eye researchers would share this view.

If the hypothesis of oblique muscle/vitreous/lens connection is confirmed, it could open the way to new techniques to prevent or slow the progression of m/lens connection is confirmed, it could open the way to new techniques to prevent or slow the progression of myopia. Further, it is not impossible that a cure for myopia could be devised, e.g. invasive techniques to reshape the curvature of the lens.

Appendix A.

As far as I know, the debate on the etiology of myopia between those who claim a hereditary basis and those who point to environmental causes still favors the former. Nevertheless, the reports of a relationship between nearwork and myopia should not be ignored. No one would dispute that the most common form of nearwork and the most "unnatural" use of the eyes is reading. Because the continuous horizontal scanning movements of the eyes in reading with downward gaze require alternate contraction and relaxation of the oblique muscles, I decided to simulate this condition in an enhanced form to determine if such contraction could produce elongation of the globe. (Actually, the axial elongation theory is an oversimplification, in that it fails to explain, for example, normal vision in elongated eyes and myopia in relatively short eyes. The investigations of Steiger (2) and others produced a shift in emphasis to the question of the variability of the different ocular components and how they interact with each other to produce emmetropia (absence of a refractive error) or ametropia (presence of a refractive error).

Because the eye muscles are not subject to individual voluntary control, it was necessary to devise some means to force the superior obliques to contract while maintaining relative relaxation of the other extraocular muscles. I thought that the natural tendency of the eyes to fuse to disparate images could be utilized for this purpose. I constructed a viewing device which contained two identical photographic transparencies depicting a visually rich pattern. When the subject looked through the device, each eye viewed one of the transparencies; the visual cortex then fuses the two images to form a single scene. The transparencies were then incyclorotated, i.e. as seen by the subject, the right-side image was rotated counterclockwise and the left-side image was rotated clockwise. In order to maintain fusion of the two images, each eye must then rotate in the same direction as the image it is viewing, i.e. the upper end of the vertical meridian of each eye leans nasalwards.

The movement of incyclorotation is effected principally by the superior oblique muscles, but there is a limit as to how far the globe can rotate, since this is opposed by the check ligaments and other fascial structures of the orbit. If an effort is made to maintain fusion, the traction of the superior obliques, which wrap part way around the globe, will exert pressure in the general area of the equatorial meridian.

The device was later modified for portable use to facilitate long-term viewing. Instead of viewing transparencies, the subject looked through a system of mirrors that tilted in like manner any scene viewed. The amount of tilt (incyclorotation) varied between 6 and 12 degrees. This is not to say that if the images are rotated, say, 8 degrees, each eye will also rotate exactly 8 degrees; eye rotation can be as much as 2 degrees less. This is because of Panum's fusional area, which in stereopsis allows the image to be pulled apart by some 2 degrees before being broken up into two separate images. The images are actually pulled apart on the retina, but a supra-retinal function maintains perception of a single image (33). In order to eliminate any stimulus to accommodation, distance fixation of at least six meters was maintained.

Because I was unable to make axial length measurements, I had to rely on changes in the visual acuity to determine if there had been any changes in axial length. Thus, if my visual acuity began to deteriorate in the course of the experiment, this could be an indication that the globe had elongated, presumably due to compression of the globe by the superior obliques.

Appendix B.

Spherical aberration

Spherical aberration is that condition in which the rays passing through a convex lens do not all come to a focus on a single point. Ivanoff (4) and others have shown that spherical aberration is normal in the human eye. When the eye is at rest the spherical aberration is positive, which means that the rays passing through the periphery of the lens come to a focus in front of rays passing through the axial region of the lens. As the lens accommodates to view a near object and begins to change its shape, the spherical aberration decreases, and at around 3 diopters there is almost no aberration at all, i.e. all the rays come to a focus at the same point. If the eye accommodates further, the aberration begins to reverse, in which case the peripheral rays come to a focus at a point behind the axial rays.

On the Use of Products Containing Aspartame (NutraSweet) by Persons with Eye Problems

by H. J. Roberts, M.D., F.A.C.P., F.C.C.P.

Professional Opinion

It is my opinion that individuals who consume products containing aspartame, including drugs and supplements, should avoid them when no specific cause can be found for the eye problems:

- Decreased vision -- including blindness in one or both eyes
- Blurring, "bright-flashes", tunnel vision, "black spots"
- Double vision
- Pain in one or both eyes
- Decreased tears
- Difficulty wearing contact lens
- Unexplained retinal detachment and bleeding

The same precaution is reasonable for persons in whom these complaints are due to other disorders because they could be aggravated by aspartame, even in minimal amounts.

- Surgery of immature cataracts should be deferred in patients who consume aspartame until after abstaining from it for 1-2 months to determine if spontaneous improvement of vision occurs.
- Impaired vision of diabetic patients should not be assumed to be due to diabetic retinopathy without such a "no aspartame test" trial.
- A similar trial is warranted in persons diagnosed as having "macular degeneration".
- The diagnosis of "early multiple sclerosis" - based on concomitant eye and neurologic features - should be deferred pending a "no aspartame test".

These corporate neutral suggestions are based on considerable observaion, research and correspondence published in more than a score of articles and two books.

- *Aspartame (NutraSweet): Is It Safe?*. Philadelphia: Charles Press, 1990.

- *Sweet'ner Dearest: Bittersweet Vignettes about Aspartame (NutraSweet)*. [Sunshine Sentinel Press](#), 1992.

I also have reviewed these and related problems in my two-cassette talk, *Is Aspartame (NutraSweet) Safe? A Medical Public Health and Legal Overview*. [Sunshine Sentinel Press](#), 1995.

These represent hard-won insights in the trenches of a medical practice. Patients and consumers should not be misled by the "negative" conclusions of flawed studies sponsored by vested interests.

There is no bias or malice intended against any company, distributor, researcher or professional who may hold contrary views.

The Role of Aspartame

Each of the components of aspartame - phenylalanine (50%); aspartic acid (40%); the methyl ester, which promptly becomes methyl alcohol or methanol (10%) - and their multiple breakdown products after exposure to heat or during prolonged storage is potentially toxic to the retina and optic nerves. These organs are highly vulnerable to metabolic disturbances and neurotoxins because of their unique metabolic requirements. Methanol causes swelling of the optic nerve and degeneration of ganglion cells in the retina.

Particular attention is directed in this regard to (1) the formaldehyde and formate (formic acid) that result from the breakdown of methyl alcohol, a severe metabolic poison, and (2) the D-aspartic acid stereoisomer.

An Overview

In my publications and in testimony to Congress and FDA advisory group, I have expressed the belief that the current wholesale ingestion of aspartame products by over half the adult population constitutes a probable "imminent public health hazard." My concern is bolstered by (1) evidence that these products may play a causative or aggravating role in many other medical disorders (including headaches, dizziness, confusion, memory loss, impaired hearing, ringing in the ears, convulsions, and probably brain tumors), (2) the flawed nature of most "scientific" studies being used to prove the alleged safety of these products, and (3) reports of serious reactions volunteered to the FDA by over 7,300 irate consumers.

In the present context, these statistics are pertinent.

- In my earlier report on 551 aspartame reactors (the data base is now 833), decreased vision was a major problem in 140 {25.4%), severe pain in 51 (8.3%), and "dry eyes" or trouble wearing contact lens in 48 (8.3%). Sixteen patients have lost vision in one or both eyes.

- The FDA (as of August 1995) had received complaints about a change in vision from 384 consumers, and "eye irritation" from 30.

These complications tend to be magnified in persons with diabetes, hypertension, unrecognized hypothyroidism (underactive thyroid), hypoglycemia (low blood sugar reactions). reaction to MSG, treatment with aspirin and other drugs that can irritate the optic and auditory nerves, persons who smoke or drink alcohol, and problems associated with aging. They become compounded by the threat of falls and driving accidents.

I welcome reports of such reactions and results of the "no aspartame test" for our independent registry. A 9-page questionnaire can be obtained by calling (407) 832-2408 or FAX (407) 832-2400.

I have also expressed concern that aspartame products might be accelerating Alzheimer's disease. The details appear in my just-published book *Defense Against Alzheimers Disease: A Rational Blueprint for Prevention*. Sunshine Sentinel Press, 1995.

Note: the following texts were provided by Elaine Fitchpatrick and Betty Martini of MISSION POSSIBLE, an organization dedicated to the eradication of NutraSweet.

The following is a letter presented before the U.S. Senate hearings on NutraSweet. It was written by Dr. Margan B. Raiford, M.D., Ps, Msc Med. Ophthalmology (Raiford 1987):

I had the opportunity, in Atlanta, Ga., to see the effects of methyl alcohol toxicity in 1952-1953 which resulted in visual damage to the optic nerves and retina in over 300 cases and the deaths of over 30 persons.

I examined Shannon Roth on July 7, 1986, along with several other patients [65 cases as of July 10, 1986 (Roberts 1990, page 136)]. I observed evidence of effects in her eye and the eyes of the other patients that were comparable to the effects observed in the patients who suffered methyl alcohol toxicity in 1952-1953.

There was damage in the central fibers, 225,000 of the total 137,000,000 optic nerve fibers (resulting in optic nerve atrophy) in her case, which would be comparable to that observed from patients suffering methyl alcohol toxicity. The extent of damage to these fibers would explain partial to total blindness.

. . . .

But in the kind of chronic low dose exposure to methyl alcohol experienced by Shannon Roth (in NutraSweet consumption) and other NutraSweet consumers, it is likely that they would experience the impact on the optic nerve differently in each eye.

The important point is that the damage observed in Shannon Roth's eye was identical to the damage I observed repeatedly in the eyes of individuals whose eyes have been damaged by methyl alcohol toxicity.

Raiford, Morgan B., 1987. Letter from Dr. Morgan B. Raiford to the Office of Senator Howard Metzenbaum. The statement was put in the record before the U.S. Senate Committee on Labor and Human Resources, November 3, 1987 regarding "NutraSweet Health and Safety Concerns." Document # Y 4.L 11/4:S.HR6.100, page 517-518.

Roberts, H.J. 1990. "Aspartame (NutraSweet): Is It Safe?" by H.J. Roberts, M.D. The Charles Press Publishers, Philadelphia, PA, c1990. Excerpt from page 91.

Dr. James Bowen, in a statement to the FDA:

Every known metabolite of aspartame is of marked or questionable toxicity and patently unsafe for human use. Methyl alcohol is metabolized to nascent formaldehyde in the eye, nervous system and other metabolically active organs. It immediately attacks and denatures the tissue structure proteins in which it is metabolized to nascent formaldehyde. This stimulates specific organ and subcellular autoimmunity which seems to be a preponderant source of the bad experiences reported by NutraSweet victims. Aspartic acid is a neuroexcitotoxin present in damaging amounts in its own right, at the ADI for aspartame. Simple logic tells one that it will vastly increase the metabolism of methyl alcohol to formaldehyde in the desinosomes of the periventricular cells of the central nervous system, thus focusing the nascent formaldehyde attack there. This corresponds well with the symptomatology often experienced, such as Lou Gehrig's Disease (ALS), bulbar palsies, neurohormonal disorders, etc. Also visual disturbances, heart palpitations, infertility and fetal loss may be traced to aspartame ingestion. The diketopiperazine issue remains totally unresolved and dangerous. The amino acids that are released by hydrolysis, from eimers and isomers that are either not sufficiently studied, or which are known substrates in undesirable pathological states such as Alzheimer's disease....

In October, 1986 the Community Nutrition Institute in Washington, D.C. filed a petition with the FDA to have it banned because of its link to blindness. Dr. H.J. Roberts was quoted in an article "Consumer Group Links NutraSweet to Blindness (*Chicago Sun Times*, Friday, October 17, 1986):

"Of 360 patients he has diagnosed as having aspartame-related problems, Roberts said, about one-fourth had decreased vision or blindness, nearly half had severe headaches and substantial numbers had epileptic seizures, confusion or memory loss, extreme depression and marked personality change."

Here's more info about methanol from an article by Dr. Ron Austin of Norwalk, California in his newsletter *Back Issues*, "NutraSweet: Friend or Foe?":

One man's (Nutra) Sweet is another man's poison! ...Methanol (methyl alcohol, wood alcohol), a poisonous substance, is added as a component during the manufacture of aspartame (NutraSweet). This methanol is subsequently released within hours of consumption in the small intestine. However, in humans this process is sped up tremendously if the methanol is ingested as a free methanol such as occurs in soft drinks after storage or in other foods after being heated. Regardless as to whether this happens or not 10% of the weight of aspartame intake of an individual will be absorbed by the bloodstream as methanol within hours after consumption. Important note: Up until date there has been no therapeutic (healing) properties of this substance (methanol) and it has been considered to be a poison. The ingestion of two (2) teaspoons is considered to be deadly in humans.

...Methyl alcohol has a selective action on the optic nerve and can cause blindness, the consumption of as little as 30 ml (two teaspoons) has caused death. Methyl alcohol is used as a polar solvent for plastics, paints, and varnishes, as an antifreeze, and in the manufacture of formaldehyde and other methyl compounds such as methyl amine, methyl chloride, and methyl methacrylate. Patients may complain of lethargy (extreme tiredness), confusion, and impairment of speech, all signs of nervous system involvement. The individual may suffer leg cramps, back pain, severe headache, abdominal pain, labored breathing, vertigo and visual loss, the latter being a very important clue to making a diagnosis of this type (methanol) poisoning. In severe cases the liver, kidneys, heart and lungs show dangerous signs of degeneration.

Dr. Austin goes on about CHRONIC OR PROLONGED EXPOSURE IN HUMANS:

Many of the signs and symptoms of intoxication due to methanol ingestion are not specific to methyl (wood) alcohol. For example, headache, ear buzzing, dizziness, nausea and unsteady gait (intoxicated or drunk type of walking), gastrointestinal disturbances, weakness, vertigo, chills, memory lapses, numbness and shooting pains in the lower extremities, hands and forearms, behavioral disturbances and neuritis. The most distinctive signs and symptoms of this type of poisoning in humans are the various visual disturbances such as: misty vision, progressive contraction of the visual fields (tunnel vision) mist before the eyes, blurring of vision and indistinct vision."

And they are having a great deal of problems with methanol even in the plants. Dr. Austin quotes one case:

A 21 year old non-drinking male who had been exposed daily to the fine dust of aspartame (NutraSweet) at the packaging plant he had been working at for over one year, was complaining of blurred vision, headaches, dizziness, and depression before his sudden death. An autopsy revealed liver, kidneys, heart and lungs degeneration (disease). The damage to the heart was as if the man had been an alcoholic between the ages of 30 and 50 and up to 50% of his food intake for over a 10 to 15 year period was alcohol. Mind you, he was a 21 year old non-drinker!! But I only have one soft drink daily with NutraSweet, surely that can't kill me, right?

Merck Index, Tenth Edition:

5816: Methanol: Methyl alcohol..wood alcohol... "Poisoning may occur from ingestion, inhalation or percutaneous absorption. Acute Effects: Headache, fatigue, nausea, visual impairment or complete blindness (may be permanently), acidosis, convulsions..respiratory failure, death. Death from ingestion of less than 30 ml. has been reported. ... Industrial solvent: Raw material for making formaldehyde and methyl esters of organic and inorganic

acids ...

Fundamentals of Chemistry by Jean Bogert, eighth edition, p 286:

"Methyl Alcohol or "wood alcohol" taken internally is a dangerous poison. It paralyzes the optic nerve and as little as 10 cc may cause blindness. Its use as a solvent in industries causes a hazard for workmen unless forced ventilation is installed, since continual breathing of the vapors, may result in blindness. A similar hazard exists when it is used as an antifreeze agent in automobile radiators, since it is vaporized by engine heat and the toxic vapor may be swept back into the car. Methyl (wood) alcohol is sometimes present in improperly prepared distilled liquors and is added to ethyl alcohol to render it unfit for beverage purposes. ("denatured alcohol").

Note: the following text was provided by Elaine Fitchpatrick and Betty Martini of MISSION POSSIBLE, an organization dedicated to the eradication of NutraSweet.

"Dry Eyes" from Use of Aspartame (NutraSweet)

Associated Insights Concerning the Sjogren Syndrome

The Townsend Letter for Doctors, Jan. 1994

by H. J. Roberts, M.D., FCCP, FACA, 300-27th St., West Palm Beach, FL 33407-5299 (407) 832-2408

"It is of use from time to time to take stock, so to speak of our knowledge of a particular disease, to see exactly where we stand in regard to it, to inquire what conclusions the accumulated facts seem to point to, and to ascertain in what direction we may look for fruitful investigations in the future." Sir William Osler

Abstract

"Dry eyes" and associated difficulty in wearing contact lenses were prominent complaints offered by 56 (8.3%) of 551 aspartame reactors. Xerostomia (dry mouth) was a frequent concomitant. The symptoms promptly improved after they stopped aspartame-containing products, and predictably recurred on aspartame rechallenge. The concomitant joint pains, severe confusion, memory loss and depression also have clinical significance, with special reference to the Sjogren syndrome.

The cause and management of "dry eyes" challenge ophthalmologists and primary care physicians. This symptom was unexpectedly and repeatedly encountered among patients manifesting other reactions to products containing aspartame, a sweetener currently being consumed by 54% of adults in the United States. This complaint was encountered in both the routine questioning of apparent aspartame reactors and a computerized, 9-page survey of such individuals. Many also volunteered difficulty in wearing contact lenses due to decreased tears, dry mouth (xerostomia), joint pains, confusion and memory loss - all specifically attributed to the use of aspartame products.

Methods

Data were obtained from 551 persons who appeared to have systemic reactions to aspartame. They consisted of 160 private patients or aspartame reactors who were personally interviewed, and 391 individuals who described their adverse side effects in the survey questionnaire...including observations after rechallenge. The names of the latter group were supplied by Aspartame Victims and Their Friends (courtesy of Mrs. Shannon Wroth), the Community Nutrition Institute (courtesy of Mr. Rod Leonard), and Dr. Woodrow Monte of Arizona State University.

The completed questionnaires were analyzed with the assistance of the Management Information System staff at the Good Samaritan Hospital, West Palm Beach, Florida.

Results

Dry eyes, ocular irritation from contact lens, or both, occurred in 46 (8.3%) aspartame reactors, In addition to the sensation of local discomfort and "sand" in the eyes, the eyelids of such patients tend to become swollen and infected, at times with loss of eyelashes.

The causative or contributory role of aspartame was indicated by these clear-cut clinical correlates: (1) prompt and gratifying improvement of ocular and other symptoms following the cessation of aspartame, generally within several days; and (2) their recurrence shortly after resuming such products. This sequence predictably recurred after rechallenge with aspartame, known or inadvertent.

These observations have been duplicated by more than a score of patients complaining of dry eyes in subsequent aspartame reactors. There were related problems. For example, a physician who consumed considerable diet sodas developed a type of corneal dystrophy generally associated with the chronic use of certain drugs (e.g., indomethacin).

Computerized correlations between aspartame-associated dry eyes, and "marked memory loss," "severe depression" and "severe mental confusion" were done on the first 362 aspartame reactors who completed the questionnaire. (There was a 30.8% response to the initial mailing of 1,177 forms.) The correlates were as follows:

- Recent aspartame-associated dry eyes and severe depression - 18 (4.9%)
- Recent aspartame-associated dry eyes and marked memory loss - 20 (5.5%)
- Recent aspartame-associated dry eyes and severe mental confusion - 9 (2.4%)

Other complaints offered by the larger cohort had considerable significance, with particular reference to the Sjogren syndrome. They included excessive thirst due to dry mouth (xerostomia) in 65 (12%), and severe joint pains in 58 (11%). It is noteworthy that three-fourths of patients in this and the large series of aspartame reactors were women averaging 50 years, a phenomenon also encountered in the Sjogren syndrome.

Representative Case Reports

Case 1 - A 47 year-old woman complained of severe dryness of the eyes that required one bottle of artificial tears a week. Her consumption of aspartame included 10-12 glasses or cups of aspartame-sweetened beverages, the addition of a tabletop sweetener to 3 cups of coffee in the morning, and considerable aspartame pudding. She also suffered confusion, significant memory loss, intense headaches (never previously a problem), impaired hearing, lightheadedness, severe "nervousness," muscle cramps, and depressions with suicidal thoughts. These symptoms markedly improved after stopping aspartame, and disappeared within several weeks. She no longer required artificial tears. Such dramatic improvement enabled her to travel abroad several weeks later with her church group for relief work.

Case 2 - A 36 year-old businesswoman complained of recent difficulty wearing contact lenses. She had been consuming considerable amounts of soft drinks and gum containing aspartame. These and other symptoms - including lightheadedness, headache and leg cramps - abated within two weeks after all aspartame products were avoided.

Case 3 - a 61 year-old female court reporter developed dry eyes and bilateral blurring of vision. Other recent complaints included marked memory loss, severe headache, dizziness, extreme irritability, and atypical facial and joint pains. As a result, she had been making many errors at work. The patient improved "immediately" when she ran out of aspartame-containing beverages, and resumed regular sodas. She therefore deduced that aspartame products had been causing her problems. Her previous daily consumption included 4 cans of aspartame soft drinks, 2 glasses of aspartame hot chocolate, and 6 packets of an aspartame tabletop sweetener.

Comment

The unexpected association of aspartame use and dry eyes offers clues concerning this symptom and the Sjogren syndrome. Other problems encountered in aspartame reactors, especially dry mouth and joint pains provide related insights.

Two reactors who complained of "thick saliva" developed enlargement and tenderness of the parotid glands. The secretory structures of the salivary glands presumably had been affected by aspartame, as well as the lacrimal glands. The affinity of aspartame for salivary glands were demonstrated experimentally by the prompt uptake of isotopically-labelled aspartame.

The Sjogren or sicca syndrome affects an estimated 2% of the adult population. The reduction or absence of lacrimal and salivary secretions results in dry eyes and dryness of the mouth. (The diagnostic lipstick-on-teeth sign consists of lipstick adhering to the upper front teeth). This disorder is presently regarded as a chronic autoimmune disorder resulting from lymphocyte-mediated destruction of these glands and changes in the points.

A vicious cycle is likely to ensue if considerable aspartame-containing beverages are consumed because of the intense thirst created by severe dryness of the mouth. Weiffenbach et al. demonstrated that taste impairment is not a necessary consequence of salivary gland dysfunction among patients with "dry mouth" caused by the chronic absence of saliva. Accordingly, such individuals may come to prefer the taste of aspartame in satisfying their chronic thirst, with perpetuation of the sicca syndrome.

The systemic and central nervous system sequelae of the Sjogren syndrome underscore the potential importance of these findings. Cognitive impairment and lamenting features have been reported by one-fourth of Sjogren patients. Severe confusion and memory loss also were noted in 157 (28.5%) aspartame reactors in the present series. Indeed, many reactors in their third and fourth decades asked, "Could I be developing early Alzheimer's disease?" The prompt and impressive regression of their confusion and memory impairment after abstinence from aspartame proved reassuring.

Several phenomenon may explain cerebral dysfunction associated with aspartame use. They include flooding of the brain with large amounts of phenylalanine (50% of the aspartame molecule), disturbances of neurotransmitters (especially dopamine), other effects of its three chemical components (phenylalanine, aspartic acid, methanol), methanol-induced cerebral edema, and glucopenia due to increased insulin release and concomitant decreased food intake in an attempt to lose weight.

For specific answers to questions about bilberry, you may call the Bilberry 20/20 Information Line at 1 800 818-9131. This service is sponsored by a company that makes bilberry extract capsules.

The following two articles are a reformatted and slightly edited version (the only textual changes are the addition of section headings, and the removal of an inappropriate apostrophe) of articles found on Robert Bidleman's [Herbal Hall](#).

[Vaccinium u.](#)

Bilberry, Huckleberry, Whortleberry, etc. by Robert Bidleman

Geography and History

Vaccinium species are found in cooler areas of North America and Eurasia, usually in moist, acid soils in wooded areas, heaths and barren places. They are especially common under canopies of old growth trees. Vaccinium leaves were used by the Kashaya Pomo in Northern California for diabetes and eye disorders, and bilberry is mentioned in many older texts in Buryatia, Europe, and China as an herb valuable for its powerful ability to correct many diseases of the digestive system, circulatory system, and eyes. For centuries bilberry has been used as a circulatory enhancer and diabetic aid (Hutchens; Moore). People of the North East USA have used blueberry leaves for diabetes for many years, and this action has been supported in at least one clinical trial (Allen).

Chemical Composition and Main Effects

Most scientific research has been done on *V. myrtillus* (bilberry). The following has been found in bilberry: ericolin, arbutin, beta-amyrin, nonacosane, and anthocyanosides. Anthocyanosides are a type of flavonoid which causes the deep blue-red color of many berries. Anthocyanosides may protect the vascular system by strengthening the capillary walls. This may produce many of the secondary benefits such as lowering of blood pressure, reduction of clots, reducing varicosities and bruising, reversing poor blood supply, and improving blood supply. Bilberry is used in Europe before surgery to prevent excessive bleeding and hemorrhaging. A recent German medical journal reports bilberry effective in reducing excessive bleeding by 71% (Lietti). Bilberry also thins the blood by inhibiting platelet adhesion

(Bottecchia). This combination of actions

1. improving capillary strength,
2. reduction of capillary leakage, and
3. blood thinning

results in improved blood flow and may reduce clotting-related health risks.

Improvement of Vision

During World War II Royal Air Force (RAF) pilots were forced to fly at night in order to accomplish any deep assault on Germany. Many pilots and their crew members complained of the poor visibility and its effects on their performance. Pilots noted that if they took bilberry jam, their night vision improved. Researchers found fifty years later what the RAF already knew, that bilberry's powerful effects increased retinal purple (rhodopsin) by dramatic amounts in just twenty minutes, sometimes less. One study showed bilberry to improve eyesight and increase ocular blood supply in 75% of patients (Sala). It improved nearsightedness after five months of regular use while an 83% improvement in visual acuity was recorded after only fifteen days. One of the more encouraging statistics regarding bilberry's visual enhancing properties is that over 80% of the people taking bilberry for the first time improved on their visual acuity exam and passed a night vision test. Long term improvements took an average of six weeks with regular doses (Sala).

Prevention of Free Radical Damage

The anthocyanosides of bilberry, which may vary in amounts from one variety to another, have been proven to be one of the more powerful antioxidants. Ranked higher in activity than vitamins E and C by Dr. Pierre Braquet, a well known phyto-researcher, anthocyanosides prevent free radical damage to collagen and collagenous tissue, making it potentially useful for diseases such as osteoarthritis, gout, and periodontal diseases. *Vaccinium myrtillus*' anthocyanosides proved consistently to increase the acetylcholine-induced relaxation of isolated coronary arteries in humans (Boniface). This is a promising update to the already impressive list of benefits of bilberry.

Improvement of Digestion

Another quality of bilberry is the effect it has on the digestive system, most notably on the stomach. A recent study showed bilberry to inhibit ulcers in 63% of patients at risk (control group, 12%) (Magistretti).

Vaccinium species have a legendary reputation as aid to an diabetics. A dual action makes it valuable in diabetes -- it improves circulation and also modifies blood sugar levels (Boniface; Magistretti). The fresh

or dried berries are useful for a feverish liver and are useful as an adjunct in stomach conditions. In Russia the berries are affectionately called by the name chernika (black ones) and are used with the leaves in tinctures for gastric colitis and other digestive problems.

Bilberry forms by Paul Bergner

Berries

Bilberries were a common food among Native Americans in all part of the continent where they grow (Erichsen-Brown). Some tribes still harvest and dry them and use them as a winter food. The berries are high in tannins (7%) (Weiss), and the resulting astringent effects makes them effective for diarrhea and dysentery. For this purpose they are taken as dried berries or as unsweetened bilberry juice.

Leaf

The leaf (tincture or tea) has been used as an antidiabetic herb for centuries. According to Weiss (Herbal Medicine) it works through the action of its constituent glucokinins, which have an insulin-like effect. He cautions that glucokinins are not some superior "plant insulin" but act indirectly through a toxic effect on the liver. He discourages long-term use.

The leaves of some species contain arbutin, and can be used like *Acrtolostaphylos uva ursi*

(bearberry) as a diuretic and urinary antiseptic. The leaves of *V. myrtillus* (bilberry) do not contain arbutin (Sticher)

Concentrated extracts

Most modern research and medicinal use has been on a highly concentrated extract, with 25% anthocyanosides, with tannins removed and using *V Myrtillus*, which does not contain arbutin (see above). The berries normally have less than 1% anthocyanosides (Kyermaten). The dose is from 180 to 800 mg a day of the extract, in three doses. The vascular effects in the accompanying article have been noted and documented with this form. Effects have been noted in improving capillary fragility, varicosities, retinal eye disorders, cataract, menstrual disorders, peptic ulcers, and atherosclerosis (Werbach and Murray).

How to Eliminate Hyperopia

by Merrill Allen, OD, PhD, FAAO, FCOVD

Humans are adaptable. The refractive error distribution in the population of newborns is almost a normal curve. By the first grade the distribution has become leptokurtic with the great majority of the population falling within -0.5 and +2.00 diopters of error. The babies have grown out of their refractive errors!

Graduate Students at Indiana University did a study of babies at 2 weeks of age who performed as well on focusing tests as college students. The one baby who did not was about 5 D hyperopic. After 6 weeks or so it was clearly withdrawn and abnormal in personality. The baby could not respond to the test. Application of +4 D glasses changed the baby's personality overnight!

Regarding the overcoming of hyperopia by optometric intervention, the baby above was not followed, but if the baby continued to wear those glasses, now as an adult, he/she will still be +4 hyperopic.

I worked with an 18 month old esotropic girl whose eyes were so crossed I thought she had convergence fixus. However when I held her at arms length and turned my body through 360 degrees her vestibulars took over and her eyes straightened and she showed nystagmus. At each of the three visits I increased the plus to take home. Her eyes straightened with +11D. Then at the age of three years while moving to another city she lost her glasses and went without them for 3 months. The new eye examination showed her Rx to be +4. She had lost 7 diopters in three months!

I did not realize the significance and was not smart enough to say to Mom: "Let's leave the glasses off for another 3 months," or "Let's wear plano glasses with binasal occluders for 3 months." The last checkup of this patient was at age 18 years when she was wearing +4D contact lenses! We cured her of esotropia and reduced 7 diopters of hyperopia! She has of course continued to be straight eyed.

Wild monkeys have low hyperopia or emmetropia and no myopia. Caged monkeys have less hyperopia and much more myopia. Because the evidence for emmetropization is so strong, I suggest a couple of approaches on how to emmetropize young hyperopes.

1. Only prescribe as much plus as needed to keep the eyes straight. (In the case of our baby that couldn't focus and had personality problems, the plus probably wouldn't be needed for more than a week or two as the child figured out how to use his eyes. At most the Rx should only be about half of the retinoscopic Rx and then reduced in power as the eyes change. With esotropia, more plus power may be needed at first to establish normal binocular vision, after which treatment of hyperopia may proceed. Alternatively for esotropia, the no Rx, binasal approach, see below, is highly recommended.

2. Use no lens power but provide binasal occluders such as frosty Scotch tape applied with the outer edges placed at the distance apart of the centers of the pupils, minus 4mm. A growing child will require frequent occluder adjustments as his/her pupillary distance increases. The binasals will straighten crossed or exotropic eyes as well as cause emmetropization. Within 6 months the occluders can be removed. Strabismus and refractive error should be cured in that time! if you or the parents forget, the child will grow out of the binasals [they will cover less and less of the visual field] and will be cured.

We know that older people grow into myopia, so I would not put an upper age on when a person can grow out of hyperopia. The important condition is that they be able to intensively pursue visual tasks requiring accommodation. If they are not visually involved, and if we eliminate the need to emmetropize, they will not emmetropize!

When I'm in the mall, I see thick glasses on small children and I have to control myself. I know that wearing those glasses blocks emmetropization. If Mom would put the glasses on the child only in the afternoon, the child would grow out of his/her hyperopia and require several spectacle power reductions. If the child's correction is less than the refractive error, he/she will grow out of the need for those glasses and soon weaker lenses will be needed.

DR. W. H. BATES DIES; AN EYE SPECIALIST

Victim, Many Years Ago of a Strange Form of Aphasia, He Disappeared Twice.

DISCOVERED VALUED DRUG

Added Suprarenal to Field of Optic Surgery -- Wrote Book, "Perfect Sight Without Glasses."

Dr. William H. Bates, a specialist in diseases of the eye, died yesterday, after a year's illness, at his residence, 210 Madison Avenue. He is survived by a widow, the former Mrs. Emily Ackerman Lierman, who had been his assistant and partner in experimental research for seventeen years before their marriage in August 1928, and by a son of the first of two earlier marriages. Dr. Bates was twice a widower.

The death of Dr. Bates recalls some years ago of his two strange disappearances, which medical men regarded as among the most remarkable instances of aphasia [sic] or loss of memory. In 1902, seven years after his graduation from the College of Physicians and Surgeons, when he was making his way rapidly in his profession and was at work on an important medical book, he vanished from the sight and knowledge of his friends. The day that he was last seen, on Aug. 30, he had written an affectionate, characteristic letter to his wife, who was then visiting her mother in Newport, and had sent her books and instruments from his apartment in the Lonsdale, 567 Madison Avenue.

When he failed to return to the apartment for several days the janitor informed Mrs. Bates, his second wife, who hurried to the city and began the search for her husband. Six weeks later she learned that he was working as an assistant in the Charing Cross Hospital, London, to which he had been taken as a patient. Mrs. Bates went to London, where she found her husband in an exhausted, nervous state, with no recollection of recent events. She took him to the Savoy Hotel, where he rested for two days and then disappeared again.

Mrs. Bates sought her husband on the Continent and in this country in vain, tracing every clue that reached her. She died before he was heard of again. How he was discovered and induced to return to New York and resume his practice has never been revealed in detail. According to the best version, a fellow-oculist, Dr. J. E. Kelly, found Dr. Bates, by accident in 1910, practicing in Grand Forks, N.D. A few months later the two men occupied offices together in this city, and thereafter Dr. Bates worked as hard and as successfully as he had done before his original disappearance.

The theories and methods of eye treatment used by Dr. Bates did not always accord with those of the majority of eye specialists. He was the originator of a method of treating imperfect eyesight by mental relaxation. He discovered the drug suprarenal, which has been called almost as valuable as cocaine in optic surgery. The best known of his books is "Perfect Sight Without Glasses."

Biography of William H. Bates

The National Cyclopaedia of American Biography, vol 24, pp. 383-4.

BATES, William Horatio, physician, was born in Newark, N.J., Dec. 23, 1860, the son of Charles and Amelia (Halsey) Bates. He was graduated A.B. at Cornell university in 1881 and received his medical degree at the college of physicians and surgeons in 1885. Establishing a practice in New York city, he served for a time as clinical assistant at the Manhattan Eye and Ear hospital and was attending physician at Bellevue hospital, 1886-88, the New York Eye infirmary, the Northern dispensary and the Northeastern dispensary, 1886-98. He was an instructor in ophthalmology at the New York Post-Graduate medical school and hospital, 1886-91. In his professional work Bates at first devoted his attention to the various organs of the head but finally restricted himself to the eye alone. He resigned his hospital appointments in 1896 and for several years engaged in experimental work. After practicing for several years at Grand Forks, N.Dak., he returned to New York and was attending physician at the Harlem hospital during 1907-22. In his researches Bates proved experimentally that the normal fixation of the eye is central, but never stationary, and the technique developed by him for treating imperfect eye sight without the use of glasses was based on this principle. From a physiological point of view, this technique was but the practical application of the psychological theory of the field of consciousness, which is predicated as a point of focus, the so-called point of apperception, surrounded by a field of increasing vagueness. His method was to develop central fixation by training the patient in the dual art of relaxing and focusing the eyes. While carrying on his experiments he developed a method of photographing the eye to reveal changes in surface curvature as the eye functioned. The work is discussed in "A Study of Images Reflected from the Cornea, Iris, Lens, and Sclera" (N.Y. Med. Jour., May 18, 1918). His researches on the influence of memory upon the function of vision are described in "Memory as an Aid to Vision" (N.Y. Med. Jour., May 24, 1919). In 1894, while seeking to determine the therapeutic effect on the eye of the active principles of the ductless glands, he discovered the stringent and hemostatic properties of the aqueous extract of the suprarenal capsule, later commercialized as adrenalin. In 1896 he announced this discovery in a paper read before the New York Academy of Medicine. He introduced a new operation for the relief of persistent deafness in 1886, consisting of puncturing or incising the ear drum membrane. He published a book, "Perfect Eyesight Without Glasses" (1919), which he had to issue at his own expense, expounding his theories which were for the most part contrary to established ophthalmological practice. He also wrote articles describing his methods. He was a member of the New York State Medical Society and was affiliated with the Dutch Reformed church. He was fond of sports, especially of tennis in which he won several awards and while living in North Dakota was state champion. He was an excellent runner and at the advanced age of fifty-eight was still able to win a prize. Bates was a quiet, modest man, a serious student of literature and astronomy, with a fondness for children. He was married three times: (1) in 1883, to Edith Kitchell of New York city, by whom he had one son, Halsey Bates; she died in 1886; (2) to Margaret Crawford, who died in 1927, leaving two children, William Crawford, and Milo Bates, wife of Charles McComb; and (3) Aug. 9,

1928, to Mrs. Emily (Ackerman) Lierman, daughter of Robert Ackerman, of Newark, N.J. Bates died in New York city, July 10, 1931.

Emanuel M. Josephson's Nutritional Theory of Myopia

Emanuel M. Josephson, MD, believed that myopia was caused by a rise in intraocular pressure. Unlike others who shared this opinion, Josephson believed that near work had nothing to do with this rise in pressure. Nonetheless, Dr. Josephson believed that myopia could be prevented by maintaining a proper "salt-water balance" in the blood through proper nutrition.

From *Glaucoma and its Medical Treatment with Cortin*, by Emanuel M. Josephson, MD, pp. 88-

MYOPIA -- ITS CAUSE AND PREVENTION

Near-sightedness, or myopia, owes its origin to the same type of disturbance in the fluid exchange of the eye as does glaucoma. This concept of the origin of myopia differs from that generally accepted; but the large mass of supporting data forces its acceptance and compels the abandonment of the older explanations.

In myopia the eyeball is too long. Parallel rays of light, coming from a distance, are brought to a focus, consequently, before they reach the retina. The victim sees only an out-of-focus blur when he looks at a distance. Concave glasses cause the light rays to diverge before entering the eye and serve to bring them to a focus on the myopic retina, correcting the near-sightedness.

The abnormally long, myopic eyeball is filled with a larger volume of fluid than the normal eye. In the more advanced cases the volume of fluid may be so great as to cause a change in the fluidity of the vitreous humor and a disruption of its structure; and may even go so far as to stretch and rupture the eyeball.

* * *

There is no dearth of clinical evidence that myopia and glaucoma are manifestations of the same underlying disease process. Most rapidly advancing cases of myopia have symptoms during the active stages of progress, similar to those of glaucoma--headaches, pain in the eye, vertigo, halo vision and others. But in the average case of myopia there generally is absent the effects of sustained pressure on the optic nerve which give rise to cupping and attendant loss of field of vision in glaucoma. This difference results from the elasticity and yield of the eyeball in myopia.

* * *

In the myopic eye, the ocular tension, as measured by a tonometer, may be very low. Even during the period of active advance of the myopia, when the amount of fluid in the eye is steadily increasing, the eye is stretching, and symptoms are acute, the tension may be in the range of low normal. Nevertheless, the stretching of the eyeball is clear evidence that the intraocular pressure exceeds the limit of resistance of the eyeball.

The tissues of the myopic eyeball are weak and distensible, and stretch under the pressure of the circulation of intra-ocular fluids. For the same reason the cornea stretches and dents deeply under the weight of the tonometer. The tonometer reading in a case of myopia is not an accurate gauge of intra-ocular fluid pressure. The situation regarding tension in these cases is the same as in the glaucoma cases which never show a rise of tension above normal levels.

The injury sustained by the tissues of the eye in myopia and glaucoma shows differences in character which reflect the difference of stretch of the eyeball. Because of the slight stretch in glaucoma, the optic nerve and other structures in the eye are compressed. In myopia, however, the stretch of the entire eyeball does not result in any such concentration of the damage, except during the periods when the eyeball resists further stretch. The greatest damage to the optic nerve and the most acute symptoms occur at these periods, which are often terminated only by actual interstitial tearing of the tissues in the eye.

From /Near-Sightedness Is Preventable/, by Emanuel M. Josephson, MD. (1939) pp. 25-26:

THE CAUSES OF NEARSIGHTEDNESS

The usual cause of organic near-sightedness is lengthening of the eyeball caused by increased volume of fluid in the eye. The disturbance of the exchange of water in the body that causes the near-sightedness is not limited to the eyes, but involves all parts of the body. For water constitutes over eighty percent of the weight of all the tissues, and a disturbance of its distribution vitally affects every part of the body. Signs of this disturbance can be recognized in every part of the body by the skilled observer.

The mechanism of control of water-exchange in the body is an extremely complicated problem concerning which much is not known. It is known that the glands of internal secretion and the autonomic nervous system play a paramount role in this mechanism. The most significant role, from the viewpoint of near-sightedness, is played by the outer part of the adrenal gland, the adrenal cortex.

The adrenal cortex influences the water exchange of the body by causing retention of salt in the blood. The determining force in the exchange of water between the blood and the

organs is their relative salt content. When the salt of the blood is reduced in quantity, water seeps, or osmoses, out of the blood into the organs. Insufficient secretion of the adrenal cortex causes such a disturbance and results in the increased flow of fluid into the eye. Thus is near-sightedness caused.

The eyes have no mechanism for controlling the amount of fluid which flows into them from the blood. They therefore succumb to every disturbance which causes increased seepage of fluid into them. As a result, there develops stretching and near-sightedness, or increased pressure and glaucoma, or other defects.

pp. 28-31

THE PREVENTION OF NEARSIGHTEDNESS

The prevention of near-sightedness hinges largely on the prevention of disturbances of the water-salt metabolism of the body. Such disturbances occur most frequently in infancy, in childhood, and at puberty. As a consequence, the prevention of near-sightedness is best begun in infancy, or even before the birth by the care of the health and diet of the expectant mother.

Malnutrition and defective diets play a large role in causing glandular disorders and the other disturbances which give rise to nearsightedness. A diet which is high in carbohydrates, starches and sugars, and low in proteins and fats, favors the development of near-sightedness. It is probable that such diets are apt to be deficient in vitamins; and that vitamin deficiency aggravates their effects.

Absence of sufficient vitamin A in the diet directly affects the status of the eye tissues. It also serves to destroy vision by depriving it of the light-sensitive visual purple upon which depends the registering of light stimuli.

Absence of the vitamin B factors from the diet, or a deficiency, results, in its extreme form, in a profound disturbance of the water-salt exchange of the body known as beri-beri. Even milder forms of this deficiency may exert profound influence on the optic nerve and vision. It also causes an increased inflow of fluid into the eye which induces either glaucoma, nearsightedness or other eye defects of this group.

Deficiency of any of a whole range of food elements influences the general health and the development of near-sightedness. The inclusion of meat or other proteins, liver, fresh green vegetables, citrus fruit and sufficient table salt, help to protect the child against the development of near-sightedness.

These facts are borne out by a survey of the dietary habits of peoples among whom nearsightedness is most widely prevalent. Port-Ricans who often live largely on a diet of rice and beans show a high incidence of near-sightedness and of other eye defects. The Germans, who present so much near-sightedness, make potatoes rather than protein-containing bread the staple of their diet.

One of the most clear-cut illustrations of the influence of diet on near-sightedness that has come under my observation was the enormous rise in the incidence among the school-children of New York City during the depression. In 1925, it was reported that 25% of the school-children attending a group of clinics in New York were afflicted with near-sightedness. With the advent of the depression, the figure rose steadily from over 40% in 1932 to 72% in 1935. Reflecting re-employment and improved nutrition in 1936, the percentage incidence of near-sightedness dropped to about 51%. In 1937, the figure dropped to 42%.

At the same time, I noted and reported a high incidence of day and night blindness among the school-children due to vitamin A deficiency, which previously was supposed to exist only in countries such as China, which suffered from chronic malnutrition. So rare had the disease been regarded by the American authorities that my report, when published in 1934, aroused considerable scepticism until it was amply confirmed by other workers.

In some cases, dietary measures are alone sufficient to prevent the development or to arrest the advance of near-sightedness. Dietary deficiencies arise, however, even in persons who have adequate diets but fail to assimilate essential food factors. This is illustrated by the case of retinitis pigmentosa.

Retinitis pigmentosa has been a blinding disease for which there was no hope. It is characterized by the early development of night-blindness which is followed by progressive and total degeneration of the retina and finally blindness. In the past, it has meant hopeless blindness. Study of the condition led me to feel that the similarity of the night-blindness to that found in vitamin A deficiency showed conclusively that retinitis pigmentosa is also a vitamin A deficiency disease. But the feeding of vitamin A brought about absolutely no improvement in these cases. Nevertheless, I felt certain that my "hunch" was correct. Finally it dawned on me that the vitamin A might not be assimilated when taken by mouth in these cases. To overcome this possible obstacle, I resorted to injection of the vitamin and its precursors into the body muscles. Improvement was startling. Vision was restored to the victims of retinitis pigmentosa, and another hopelessly blinding disease was conquered. (*Nature*, Jan. 23, 1937)

Reliance, therefore, cannot be placed in the mere presence of vitamins and of other requisite elements in the diet. If near-sightedness and other deficiency-caused defects are to be averted, it must be made certain that the body is properly utilizing those elements.

A word of comment is in order on the denaturing of food by our modern methods of processing. This plays as large a role in the production of near-sightedness as in other diseases.

Extraocular Muscles and their Effect on the Shape of the Eye

The following works, two centuries old, provide evidence that accommodation of the eye to different distances is a result of the [extraocular muscles](#) changing the shape of the cornea or of the eye as a whole. They are reprinted from Philosophical Transactions of the Royal Society of London, 1794-1802. Conspicuously absent from this collection is the work by Thomas Young, whose theory that was the lens and the lens only changes in shape during accommodation. He published two articles in defense of his theory, one in 1794, and another (his most famous and widely cited), in 1801. Young's theory is the only one that prevails today in "scientific" circles, with the exception that Young thought the lens to contain muscles, and now the ciliary muscles are said to be responsible for controlling the lens's shape, as was proposed by Hermann von Helmholtz in the 1840s.

- Mr. Pierce Smith. "[Observations on the Structure of the Eyes of Birds.](#)" And mammals for that matter. The author examines the interface between the recti muscles and cornea in birds and quadrupeds. Considerations about the human eye are also given. Illustrated. (Published 1795)
- David Hosack, MD. "[Observations on Vision.](#)" An argument that the extraocular muscles are responsible for accommodation in humans. Illustrated. (Published 1794)
- Everard Home, Esq.: The Croonian Lectures on Muscular Motion.
 - [1794 Croonian Lecture.](#) Anatomical and experimental evidence that the cornea changes during the eye's adjustment to different distances; extraocular muscles must be involved. Illustrated. (Published 1795)
 - [1795 Croonian Lecture.](#) Further evidence for corneal change during accommodation. Theory expanded to include movement of lens and elongation of eye via ciliary and extraocular muscles Illustrated. (Published 1796)
 - [1801 Croonian Lecture.](#) Demonstration of accommodation in various lensless eyes. (Published 1802)

While most have abandoned the theory that the cornea is a dynamic part of the eye, a few 20th century experiments support the idea that the cornea changes more rapidly than is usually assumed.

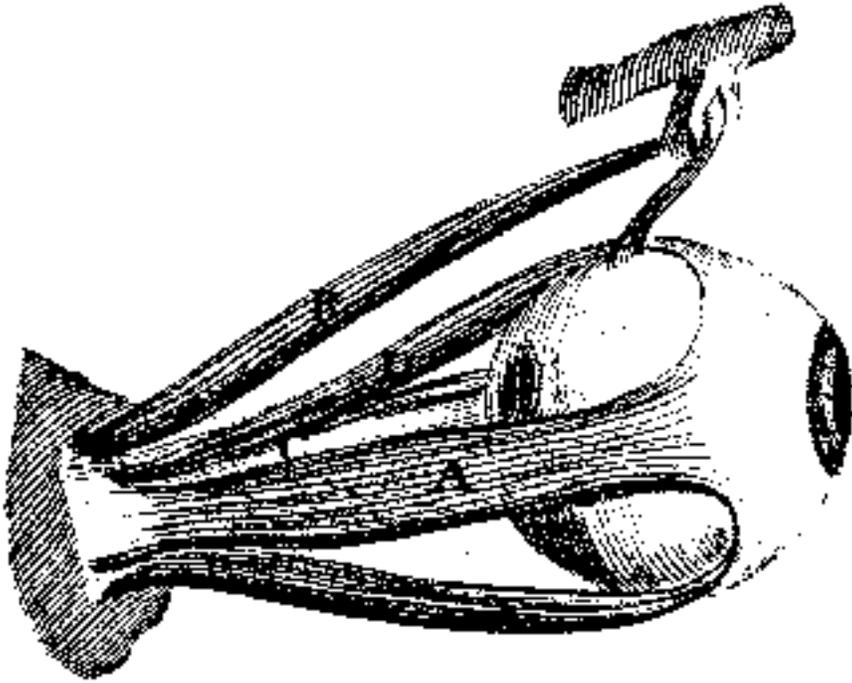

In 1931 Optometrist J.W. Parker wrote an article on instant [Changes in Corneal Astigmatism](#) evidently produced by the extraocular muscles.

Fig. 9.

Observations on the Structure of the eyes of Birds.

By Mr. Pierce Smith, Student of Physic. From *Philosophical Transactions of the Royal Society of London*, vol. 85 (1795), pp. 263ff

In March, 1792, I observed, while dissecting the eyes of birds, an irregular appearance of the sclerotica, in that part of it which immediately surrounds the cornea, and which in them is generally flat. On a more minute examination, it appeared to be scales lying over each other, and which appeared capable of motion on each other. These appearances I showed to Dr. Fowler of London, and to Mr. Thomson, surgeon, Edinburgh. In June, this paper was copied out at my request, by Mr. Irving, who resided in the same house with me. On investigating this singular structure, the scales were found to be of bony hardness, at least much more so than any other part of the sclerotica. On the inside of the sclerotic coat of the eye there was no appearance of these scales, that part of it being similar to the rest of the sclerotica. Tendinous fibres were detected, spreading over the scales, and terminating at last in forming the 4 recti muscles belonging to the eye; so that on the contraction of these muscles) motion of the scales would be produced. This imbricated appearance, and the detection of the tendinous fibres spreading over scales terminating at last in the 4 recti muscles, led me to consider the use of this structure, what would be the effect of motion of the scales on the vision of birds, and how far this can be applied to other animals.

It is a fact so well known to persons acquainted with optics, that it is almost unnecessary to mention it, that the rays of light passing through a lens, will be refracted to a point or focus beyond the lens and this focus will be less distant in proportion as the lens approaches a sphere in shape. Now this principle is very naturally applied to the explanation of the use of this apparatus. These scales lying each partly over the next, so as to allow of motion, will on the contraction of the recti muscles inserted into and covering them, move over each other, and thus the circle of the sclerotica, will be diminished, and of course the cornea which is immediately within the circle made by these scales will lie pressed forwards, or in other words rendered more convex, and thus the focus of the eye becomes altered, its axis being elongated. This construction and consequent convexity of the cornea, must render small objects near the animal very distinct. On the muscles relaxing, the elasticity of the sclerotic coat will restore the cornea to its original flatness; it thus becomes fitted for viewing objects placed at a greater distance from the eye, and this will be in proportion to the degree of relaxation.

There seems to exist in nature an economy of motion, to prevent fatigue and exhaustion of the animal powers, by continued voluntary muscular motion. If 2 opposite actions of the same frequency occur in 2 muscles, the one being antagonist to the other, the action of one ceasing, the action of the other must take place previously to further motion of the part; for instance, on the biceps flexor of the arm acting, the arm

will be bent, but on discontinuing its action the arm will remain in the same state, unless it was straightened by the action of the biceps extensor its antagonist; but where one action in a part is required to take place almost constantly, and the opposite action but seldom, to save the animal from fatigue, necessarily induced by muscular contraction, she gives an elastic ligament, which from its elasticity may be said to be in continual motion without exhausting the animal. Thus when the opposite action which is of less frequent occurrence is required, it is performed by overcoming the resistance, or elasticity of this elastic ligament, which on the muscle giving over its action again, resumes its former state. The elastic cartilages of the ribs performing in some degree the function of a muscle, are of use in respiration; likewise the elastic ligaments which support the claws of all the feline genus, keeping them from friction against the ground. These claws at the volition of the animal, by muscles appropriated for that purpose, are brought into action or extended. From the above-mentioned structure, the same thing appears to take place in the eyes of animals. When an animal is desirous of seeing minute objects, the recti muscles act, and thus, by rendering the eye more convex enlarge the angle under which the object is seen. How necessary is this structure to these animals in particular; for without it a bird would be continually exposed to have its head dashed against a tree when flying in a thick forest, its motions being too rapid for the common structure of the eye. The eagle, when soaring high in the air, observes small objects on the earth below him, inconceivable to us, and darts upon them instantaneously. Here we must allow that there must be an extraordinary alteration in the focus of this eye in almost an instant of time. How could this be performed unless the animal had this apparatus? The eyes of quadrupeds, as I shall afterwards show, can perform this alteration; though not in the same degree, as it is not necessary, their modes of life being different. A swallow sailing through the air pursues a gnat or small fly to almost certain destruction. This apparatus is very distinct in all these birds. Whenever we find the subsistence or safety of an animal entrusted to, or depending more particularly on one sense than the rest, we are sure to find that sense proportionably perfect; as in quadrupeds the organ of smelling is remarkably perfect, and leads them to their prey; so the eyes of birds are proportionably perfect, being the means not only of their support, but from them they receive the first intimation of approaching danger.

The eyes of birds like those of other animals, consist of 3 coats, the sclerotica, choroides, and retina. The human eye, as well as those of quadrupeds, is nearly spherical; in birds the sphere is more oblate, the sclerotica as it approaches the cornea becoming suddenly flat. The cornea, though small when compared with the size of the whole eye, is more convex as it forms the segment of a smaller circle, added to the larger, formed by the sclerotica. The reason or advantage of this flatness is not very evident. It prevents them perhaps from projecting so far as to expose them to danger from the trees and grass, among which these animals live.

As no description, however accurate, can give an idea of the structure of any part of the animal body, I have caused small sketches to be made explaining all the different circumstances mentioned in the paper.

After having examined the eyes of birds, and seeing this curious apparatus, I was next led to the examination of the eyes of quadrupeds, that I might see in what manner they resembled the eyes of birds, and if I could account for their being able to accommodate their eyes to objects at different distances.

This was a subject involved in much difficulty, as the eyes of quadrupeds appeared on examination not to

have these imbricated scales, which are so obvious in birds; but all this difficulty vanished on taking hold of one of the 4 recti muscles of the eye of a sheep; and by tearing and dissecting, I found that it terminated in, and with the other parts composed the cornea; so that on the first volition of the mind the recti muscles on contracting will have the power of fixing the eye and keeping it steady, and at the same time by contracting more or less, will adapt the focus of the eye to the distance of the object, but in a less degree than in birds. On these muscles giving over acting, the eye will be restored to its former state by the elasticity of the sclerotic coat.

From a knowledge of these circumstances, we may from rational principles explain, why people by being long accustomed to view small objects, obtain in time a sort of microscopic power, if it may be so called; that is, the muscles which contract the cornea will by custom increase their power of action, and grow stronger, like the other muscles of the body. Other phenomena of vision on these principles may be explained.

Structure of Birds' Eyes. Pa. 559.

Fig. 1.

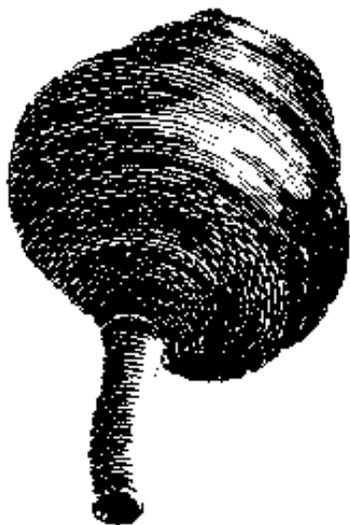

Fig. 2.

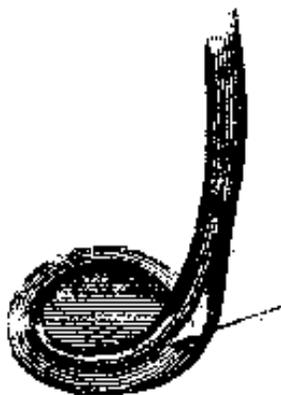

Fig. 3.

Fig. 4.

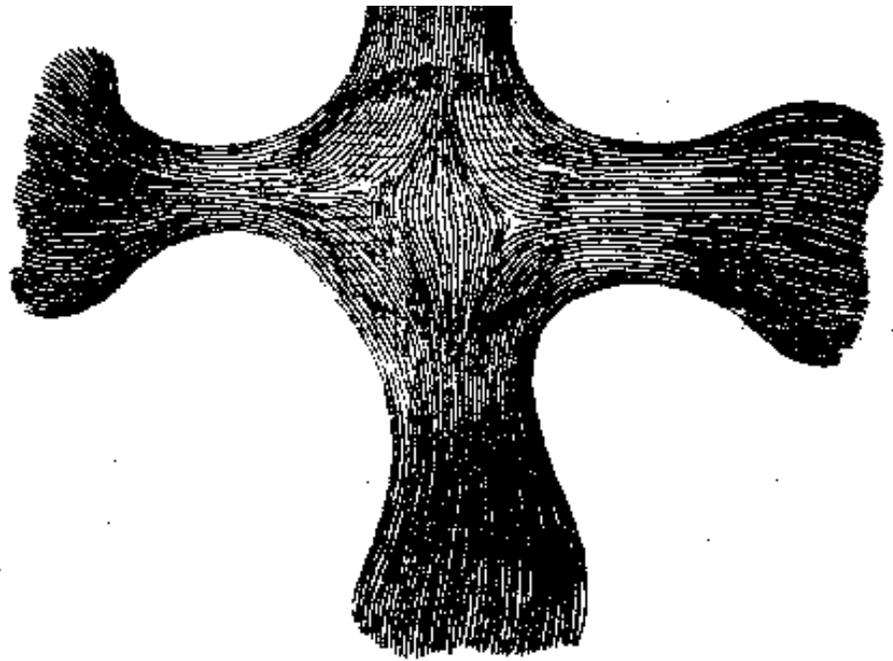

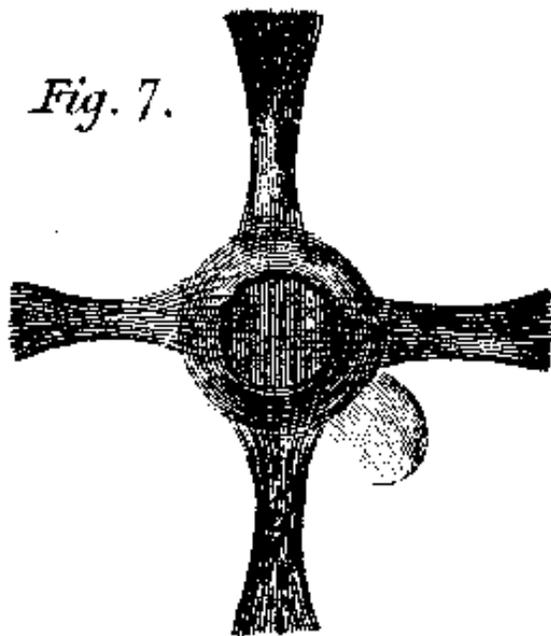

Fig. 5.

Fig. 6.

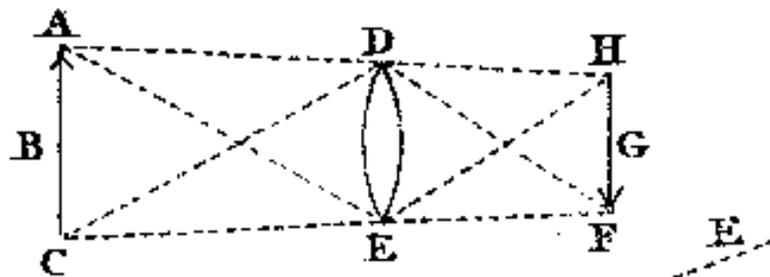

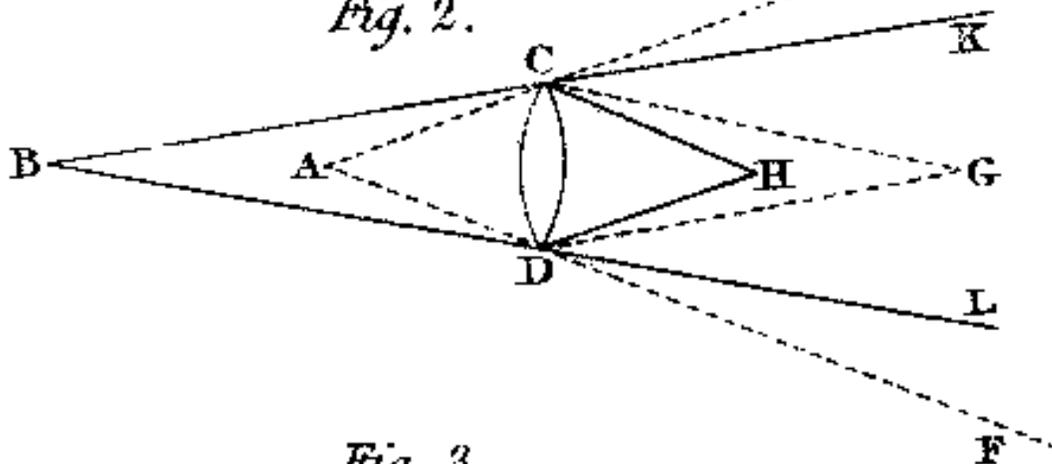

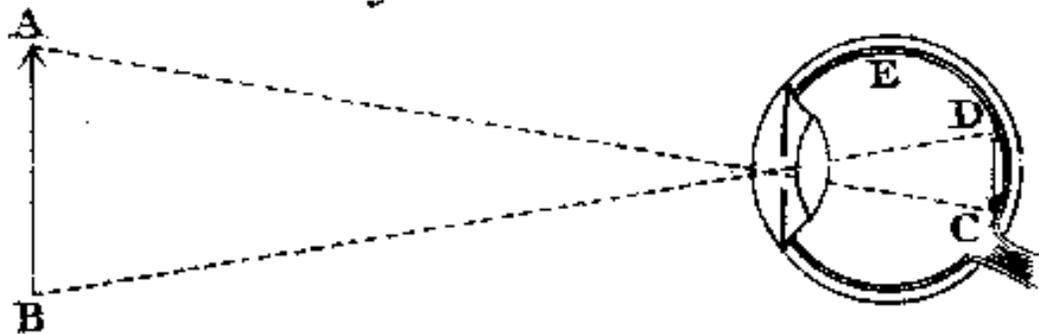

- Fig. 1, represents the eye of a buzzard, blown up and dried, the lesser circle of the cornea suddenly rising above the sclerotic coats.
- Fig. 2, one of the recti muscles, dissected in such a manner as to show that a part of it is inserted into, and the rest of the muscle going from, the outer coat of the cornea.
- Fig. 3, is a representation of the imbricated or loricated appearance of the scales which cover part of the sclerotic coat of the eye, divested of its muscles.
- Fig. 4, shows that the scaly appearance is weaker in some birds than in others, according to their different modes of life, more so in the turkey than in the buzzard, (see fig. 3) representing likewise one of the recti muscles attached to the scales.
- Fig. 5, the inside view of these scales in the eye of a turkey, the internal coat of the cornea being torn up or separated from the external.
- Fig. 6, the 4 recti muscles in the eye of the sheep, dissected so as to show their fibres inserted into and going to form the outer coat of the cornea.
- Fig. 7, the 4 recti muscles of the eye of the turkey, which are partly inserted into and running to form part of the outer coat of the cornea.

Observations on Vision

by David Hosack, M.D. From *Philosophical Transactions of the Royal Society of London*, vol. 84 (1794), pp. 196 ff.

By what power is the eye enabled to view objects distinctly at different distances? [...]

1st. Let ABC [fig 1] be an object placed before the double convex lens DE, at any distance greater than the radius of the sphere of which the lens is a segment: the rays which issue from the different points of the object, and fall on the lens, will be so bent by the refractive power of the glass, as to be made to convene as many other points behind the lens, and at the place of their concurrence they will form an image or picture of the object. The distance of the image behind the glass varies in proportion to the distance of the object before the glass; the image approaching as the object recedes, and receding as that approaches.

Fig. 1. Pa. 403.*Fig. 2.**Fig. 3.*

For if we suppose [fig 2] A and B two radiating points, from which the rays AC, AD, and BC, BD, fall on the lens CD, it is manifest that the rays from the nearest point A diverge more than those from the more distant point B, the angle at A being greater than that of B; consequently the rays from A, whose direction is AE and AF when they pass through the glass, most convene at some point, as G., more distant from the lens than the point H, where the less diverging rays BK and BL from the point B are made to convene; which may also be proved by experiment with the common convex glass. It will be necessary to have this proposition in view, as we shall afterwards have occasion to use it in showing, that by varying the distance between the retina and the anterior part of the eye, we are enabled to see objects at different distances.

2d. If an object, as AB (fig. 3) be placed at a proper distance before the eye, E, the rays which fall from the several point of the object falling on the cornea pass through the pupil, and will be brought together by the refractive power of the different parts of the eye on as many corresponding points of the retina, and

there paint the image of the object, in the same manner as the images of objects placed before a convex lens are painted on the spectrum, placed at a proper distance behind it: thus, the rays which flow from the point A are united on the retina at C, and those which proceed from B are collected at D, and the rays from all the intermediate points are convened at as many intermediate points of the retina: on this union of the rays at the retina depends distinct vision. But supposing the eye of a given form, should the point of union lie beyond the retina, as must be the case with those from the less distant object, agreeable to the preceding proposition; or should they be united before they arrive at the retina, as from the more distant object, it is evident that the picture at the retina must be extremely confused. Now as the rays which fall on the eye from radiating points at different distances, have different degrees of divergence, and the divergence of the rays increasing as the distance of the radiating point lessens, and vice versa, lessening as that increases; again, as those rays which have greater degrees of divergence, viz. from the nearer objects, require a stronger refractive power to bring them together at a given distance, than what is necessary to make those meet which diverge less, it is manifest, that to see objects distinctly at different distances, either the refractive power of the eye must be increased or diminished, or the distance between the iris and retina be varied, corresponding with the different distances of the objects; both of which probably take place, as will hereafter appear.

[Argument against the muscularity of the lens deleted]

That it is not from any changes of the lens, and that this is not the most essential organ in viewing objects at different distances, we may also infer from this undeniable fact, that we can in a great degree do without it; as after couching or extraction, by which operations all its parts must be destroyed, capsule, ciliary process, muscles, &c. Mr. Young asserts, from the authority of Dr. Porterfield, that patients, after the operation of couching, have not the power of accommodating the eye to the different distances of objects; at present I believe the contrary fact is almost universally asserted:

"Et lente ob cataractam extractam vel depositam oculum tamen ad varias distantias videre, ut in nobili viro video absque allo experimento que eam facultatem recuperaverit. Etsi enim tunc ob diminutas vires quae radios uniunt, aeger lente vitrea opus habet, eadem tamen lens in omni distantia sufficit." -- Haller, *El. Phys.*

"La lentille cristalline n'est cependant point de première nécessité pour la vision. Aujourd'hui, dans l'opération de la cataracte on l'enlève entièrement, et la vision n'en souffre point." *De la Méthode des Vues Physiologiques*. See also *De la Hire, Hamberger Physiolog.*

Besides, if the other powers of the eye are insufficient to compensate for the loss of this dense medium, the lens, a glass of the same shape answers the purpose, and which certainly does not act by changing its figure. I grant their vision is not so perfect; but we have other circumstances on which this can be more easily explained; which will be particularly noticed under the next head. It may not be improper also to observe, that the specific gravity of the crystalline compared with that of the vitreous humour, and of

consequence its density and power of refraction, is not so great as has been generally believed. Dr. Bryant Robinson, by the hydrostatic balance, found it to be nearly as 11 to 10. I have also examined them with the instrument of Mr. Schmeisser, lately presented to the R.S., and found the same result; of consequence the crystalline lens is not so essentially necessary for vision as has been represented, especially as it is also probable, that on removing it, the place which it occupied is again filled by the vitreous humour, whose power of refraction is nearly equal. At the same time we cannot suppose the lens an unnecessary organ in the eye, for nature produces nothing in vain; but that it is not of that indispensable importance writers on optics have taught us to believe. ...

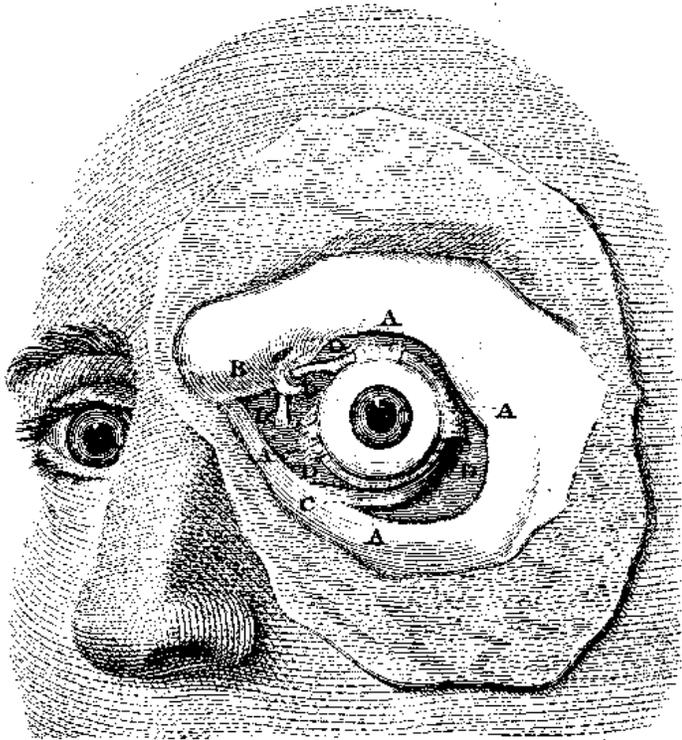

Another opinion has been sanctioned by many respectable writers, of the effects of the ciliary processes in changing the shape and situation of the lens; some supposed it to possess the power of changing the figure of the crystalline, rendering it more or less convex (Des Cartes, Scheinerus, Bidlous, Mollinettus, Sanctorius, Jurin); others, that it removed it nearer to the cornea (Kepler, Zinn, Porterfield); and thers, that it removed it nearer the retina (La Chariere, Perrault, Hartsoeker, Brisseau, and Derham). The advocates for these different opinions all agree in attributing these effects to a supposed muscularity of the ciliary processes. Of the structure of these processes Haller observes 'In omni certe animalium genere processus ciliares absque ulla muscosa sunt fabrica, mere vasculosi vasculis serpentinis percursi molli facti membrana.' Which structure I believe at present is universally admitted. But even supposing them muscular, such is their delicacy of structure, their attachment and direction, that we cannot possibly conceive them adequate to the effects ascribed to them. Besides ... they may be destroyed, as in couching or extraction, and yet the eye be capable of adapting itself to the different distances of objects. For a more full refutation of these opinions, see Haller's large work.

On the situation, Structure, and Action of the External Muscles.

For the accuracy of the representation I have annexed (in figs. 7, 8, 9,) I can vouch, having been at much pains in the dissection; from which I had the painting taken by a most accurate hand, Mr. S. Edwards, a gentleman well known for his abilities in the plates of that admirable work, the Flora Londinensis.

On carefully removing the eyelids, with their muscles, we are presented with the muscles of the eye itself, which are 6 in number; 4 called recti, or straight; and 2 oblique; so named from their direction (see fig. 7) AA AA, the tendons of the recti muscles, where they are inserted into the sclerotic coat, at the anterior part of the eye. B, the superior oblique, or trochlearis, as sometimes called, from its passing through the loop or pulley connected to the lower angle of the orbiter notch in the os frontis; it passes under the superior rectus muscle, and backwards to the posterior part of the eye, where it is inserted by a broad flat tendon into the sclerotic coat. C, the inferior oblique, arising tendinous from the edge of the orbiter process of the superior maxillary bone, passes strong and fleshy over the inferior rectus, and backwards under the abductor to the posterior part of the eye, where it is also inserted by a broad flat tendon into the sclerotic coat. DDD, the fat in which the eye is lodged.

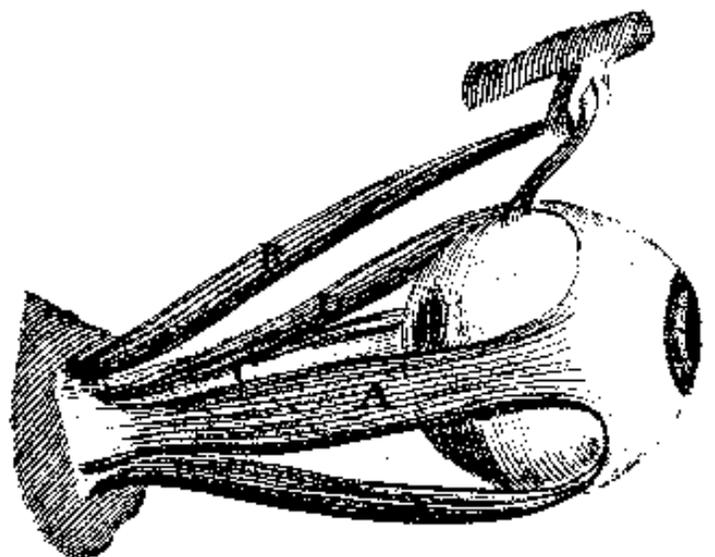

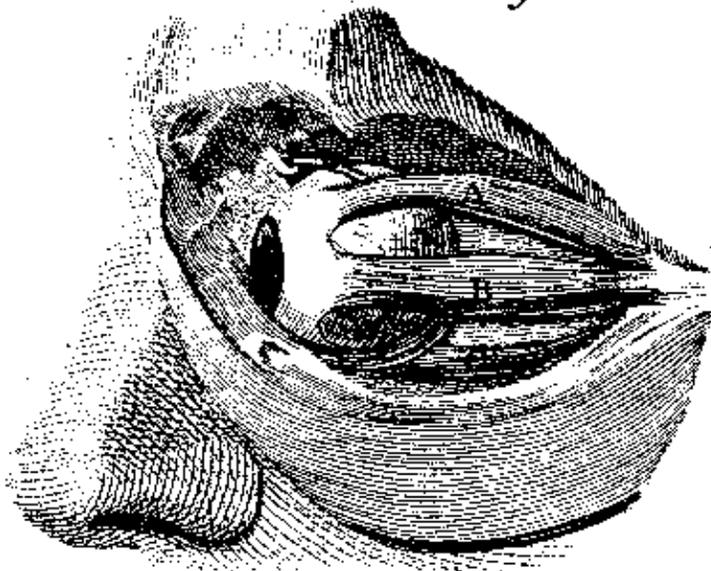

Fig. 7.

In Fig. 8, we have removed the bones forming the external side of the orbit, with a portion of the fat, by which we have a distinct view of the abductor. ABC, 3 of the recti muscles, arising from the back part of the orbit, passing strong, broad and fleshy over the ball of the eye, and inserted by flat, broad tendons into the sclerotic coat, at its anterior part. D, the tendon of the superior oblique muscle. E, the inferior oblique, fig. 9. A, the abductor of the eye. B, the fleshy belly of the superior oblique, arising strong, tendinous, and fleshy from the back part of the orbit. C, the optic nerve. D and E, the recti muscles.

Fig. 9.

Fig. 8.

The use ascribed to these different muscles, is that of changing the direction of the eye, to turn it upwards, downwards, laterally, or in any of the intermediate directions, accommodated either to the different situation of objects, or to express the different passions of the mind, for which they are peculiarly adapted. But is it inconsistent with the general laws of nature, or even with the animal economy, that from their combination they should have a different action, and thus an additional use? To illustrate this we need only witness the action of almost any set of muscles in the body; for example, in lifting a weight, the combined action of the muscles of the arm, shoulder, and chest, is different from the individual action of either set, or of any individual muscle; or an instance nearer our purpose may be adduced, viz. the actions of the muscles of the chest and belly, making a compression on the viscera, as in the discharge of urine, foeces, &c. But to question this fact would be to question the influence of the will in any one of the almost infinite variety of motions in the human body.

I presume therefore it will be admitted that we have the same power over these muscles of the eye as of others, and I believe we are no less sensible of their combined action; for example, after viewing an object at the distance of half a mile, if we direct our attention to an object but 10 feet distance, every person must be sensible of some exertion; and if our attention be continued but for a short time, a degree of uneasiness and even pain in the ball of the eye is experienced; if again we view an object within the focal distance, i.e. within 6 or 7 inches, such is the intensity of the pain that the exertion can be continued but a very short time, and we again relieve it by looking at the more distant objects; this I believe must be the experience of every person whose eyes are in the natural and healthy state, and accordingly has been observed by almost every writer on optics. But the power of this combination, even from analogy, appears too obvious to need further illustration. I shall therefore next endeavour to point out their precise action.

Supposing the eye in its horizontal natural position; I see an object distinctly at the distance of 6 feet, the picture of the object falls exactly on the retina; I now direct my attention to an object at the distance of 6 inches, as nearly as possible in the same line; though the rays from the first object still fall on my eye, while viewing the 2d, it does not form a distinct picture on the retina, though at the same distance as before, which shows that the eye has undergone some change; for while I was viewing the first object I did not see the 2d distinctly, though in the same line: and now, vice versa, I see the 2d distinctly, and not the first; the rays from the first therefore, as they still fall on the eye, must either meet before or behind the retina; but we have shown that the rays from the more distant object convene sooner than those from the less distant object, therefore the picture of the object at 6 feet falls before, while the other forms a distinct image on the retina; but as my eye is still in the same place as at first, the retina has by some means or other been removed to a greater distance from the fore part of the eye to receive the picture of the nearer object, agreeable to the principle before-mentioned. From which it is evident, that to see the less distant object, either the retina should be removed to a greater distance or the refracting power of the media should be increased: but I hope we have shown that the lens, which is the greatest refracting medium, has no power of changing itself.

Let us next inquire, if the external muscles, the only remaining power the eye possesses, are capable of producing those changes. With respect to the anterior part of the eye, we have seen the situation of those muscles; the recti strong, broad and flat, arising from the back part of the orbit, passing over the ball as

over a pulley, and inserted by broad flat tendons at the anterior part of the eye; the oblique inserted toward the posterior part, also by broad flat tendons; when they act jointly, the eye being in its horizontal position, it is obvious, as every muscle in action contracts itself, the 4 recti by their combination must necessarily make a compression on the different parts of the eye, and thus elongate its axis, while the oblique muscles serve to keep the eye in its proper direction and situation. For my own part, I have no more difficulty in conceiving of this combination of those muscles, than I have at present of the different flexors of my fingers in holding my pen. But other corresponding effects are also produced by this action; not only the distance between the anterior and posterior parts of the eye is increased, but of consequence the convexity of the cornea, from its great elasticity, is also increased, and that in proportion to the degree of pressure by which the rays of light, passing through it, are thence necessarily more converged. But another effect, and one not inconsiderable, is that by this elongation of the eye, the media, viz. the aqueous, crystalline, and vitreous humours through which the rays pass, are also lengthened, of consequence their powers of refraction are proportionably increased; all which correspond with the general principle. It may however be said, that as the 4 recti muscles are larger and stronger than the 2 oblique, the action of the former would overcome that of the latter, and thus draw back the whole globe of the eye; but does not the fat at the posterior part of the orbit also afford a resistance to the too great action of the recti muscles, especially as it is of a firm consistence, and the eye rests immediately on it? Admitting then that this is the operation of the external muscles when in a state of contraction, it is also to be observed that we have the same power of relaxing them, in proportion to the greater distance of the object, till we arrive at the utmost extent of indolent vision.

But, as a further testimony of what has been advanced, I had recourse to the following experiment, which will show that the eye is easily compressible, and that the effects produced correspond with the principles I have endeavoured to illustrate. With the common speculum oculi I made a very moderate degree of pressure on my eye, while directing my attention to an object at the distance of about 20 yards; I saw it distinctly, as also the different intermediate objects; but endeavouring to look beyond it, every thing appeared confused. I then increased the pressure considerably, in consequence of which I was enabled to see objects distinctly at much nearer than the natural focal distance; for example, I held before my eye, at the distance of about 2 inches, a printed book; in the natural state of the eye I could neither distinguish the lines nor letters; but on making pressure with the speculum I was enabled to distinguish both lines and letters of the book with ease.

Such then I conceive to be the action and effects of the external muscles, and which I apprehend will also apply in explaining many other phaenomena of vision; some of those it will not be improper at present briefly to notice. First, may not the action of those muscles have more or less effect in producing the changes of vision which take place in the different periods of life? At the same time the original conformation of the eye, the diminution of its humours, and probably of the quantity of fat on which the eye is lodged, are also to be taken into the account. But the external muscles becoming irregular and debilitated by old age, in common with every other muscle of the body, are not only incapable of compensating for these losses, but cannot even perform their wonted action, and thus necessarily have considerable influence in impairing vision. Again, does not the habit of long sight so remarkable in sailors and sportsmen, who are as much accustomed to view objects at a great distance, and that of short sight, as of watchmakers, seal-cutters, &c. admit of an easy solution on this principle? as we know of no

part of the body so susceptible of an habitual action as the muscular fibre.

2dly, How are we to account for the weaker action of one eye in the case of squinting [cross-eye]? That this is the fact has been well ascertained; Dr. Reid (See his Inquiry into the Human Mind, page 322) on this subject observes, that he has examined over 20 persons that squinted, and found in all of them a defect in the sight of one eye. Porterfield and Jurin have made the same observation. The distorted position of the eye has I believe been generally attributed to the external muscles; but no satisfactory reason has ever been given why the eye, directed towards an object, does not see it distinctly at the same distance as with the other. The state of the iris here cannot explain it, as it contracts and dilates in common with the other, nor can we suppose any muscles the lens might possess could have any effect, as they are not at all connected with the nature of this disease.

But the action of the external muscles, I apprehend, will afford us a satisfactory explanation. When the eye is turned from its natural direction, for example, towards the inner canthus, it is obvious that the adductor muscle is shortened, and its antagonist, the abductor, lengthened; consequently, as the abductor has not the same power of contracting itself with the adductor, when the eye is directed towards an object, their power of action being different and irregular, the compression made on the eye and its humours must also be equally irregular, and therefore insufficient to produce the regular changes in the refraction and shape of the eye we have shown to be necessary in adapting it to the different distances of objects. The effects produced by making a partial pressure on the eye with the finger, or speculum oculi, before noticed, would also appear to favour this explanation.

3dly, May it not in part be owing to the loss of this combined action of the external muscles, and the difficulty of recovering it, that the operation of couching is sometimes unsuccessful, especially when the cataract has been of long standing? This cannot be attributed to the iris, for it perhaps dilates and contracts as before: nor to the muscles of the lens, for they are removed; nor to the state of the nerve, for it is still sensible to light; and yet the patient cannot see objects distinctly; and it is not an uncommon circumstance, even when the operation succeeds, that the sight is slowly and gradually recovered. Instances have occurred, Mr. Bell (see his System of Surgery) observes, of the sight becoming gradually better for several months after the operation. When we have been long out of the habit of combining our muscles in almost any one action of life, as walking, dancing, or playing on a musical instrument, we in a great measure lose the combination, and find a difficulty in recovering it, in proportion to the length of time we had been deprived of it; but the individual action of each muscle remains as before. Thus probably with the muscles of the eye. A variety of facts of a similar nature must present themselves to every person conversant in the science of optics, which may admit of a similar explanation.

I have thus endeavoured first, to point out the limited action of the iris, and of consequence the insufficiency of this action for explaining vision. 2dly, to prove that the lens possesses no power of changing its form to the different distances of objects. 3dly, that to see objects at different distances, corresponding changes of distance should be produced between the retina and the anterior part of the eye, as also in the refracting powers of the media through which the rays of light are to pass. And 4thly, that the combined action of the external muscles is not only capable of producing these effects, but that from their situation and structure they are also peculiarly adapted to produce them. Is it not then consistent

with every principle in the economy of nature and philosophy, seeing the imperfections of the principles which have hitherto been employed in explaining the phenomena in question, to adopt the one before us, till, agreeable to one of the established rules in philosophizing, other phenomena occur, by which it may be rendered either more general, or liable to objections?

I have now finished what was proposed. I have declined entering into an extensive view of the structure of the eye, or any of the general principles of optics, as those subjects have been more ably treated in the works already cited, and thus would certainly have destroyed every claim to attention, which these few pages in their present form may possibly possess; and if I should be so fortunate as to succeed in establishing the principle I have proposed, for explaining the phenomena dependent on this more important organ of our body, if any part possesses a pre-eminence in nature, I also hope it may, in abler hands, admit of some practical application, in alleviating the diseases to which its delicate organization so particularly exposes it.

Since the above pages have been written, I have found, on consulting some of the earliest writers, that the effects of the external muscles did not altogether escape their attention; at the same time they had no distinct idea of their action: I must therefore disclaim the originality of the thought, though I had never met with it before the circumstances already noticed, of the insufficiency of the iris, had suggested it. If however, I have succeeded in pointing out the precise action of those muscles, and its application to the general principles of vision, in which I believe I have never been anticipated, it will be the height of my wishes.

The (1794) Croonian Lecture on Muscular Motion.

By Everard Home, Esq. F.R.S. From *Philosophical Transactions of the Royal Society of London*, vol. 85 (1795), pp. 1ff.

When I had the honour last year of presenting an apology for the unfinished state in which Mr. Hunter left the Croonian lecture, I laid before the R.S. the plan on which he meant to proceed; but my mind was at that time unfitted to prosecute so arduous an inquiry. The progress Mr. Hunter had made in this investigation enabled him to prove the crystalline humour of the eye to be laminated, and the laminae to be composed of fibres; but the use to which these fibres are applied in the economy of the eye he had not ascertained, though several experiments were instituted with that view: his opinion was certainly in favour of their being muscular, for the purpose of adjusting the eye to different distances by their contraction and relaxation.

Being unwilling that a subject on which Mr. Hunter had so publicly given his opinion should remain in an unfinished state, I requested the President's permission to be allowed to give the Croonian lecture for the present year, as it would afford me an opportunity of weighing with impartiality the facts already ascertained, and of endeavouring by my own labours to add to their number. In prosecuting this inquiry, I consider myself to have been particularly fortunate in having had the assistance of Mr. Ramsden. It was a subject connected with his own pursuits, and one which had always engaged his attention; he was therefore peculiarly fitted, both by his own ingenuity and knowledge in optics, for such an investigation. In conversing on the different uses of the crystalline humour, he made the following observations.

He said, that as the crystalline humour consists of a substance of different densities, the central parts being the most compact, and from thence diminishing in density gradually in every direction, approaching the vitreous humour on one side, and the aqueous humor on the other, its refractive power becomes nearly the same with that of the 2 contiguous substances. That some philosophers have stated the use of the crystalline humour to be, for accommodating the eye to see objects at different distances; but the firmness of the central part, and the very small difference between its refractive power near the circumference and that of the vitreous, or the aqueous humour, seemed to render it unfit for that purpose; its principal use rather appearing to be for correcting the aberration arising from the spherical figure of the cornea, where the principal part of the refraction takes place, producing the same effect that in an achromatic object glass we obtain in a less perfect manner, by proportioning the radii of curvature of the different lenses. In the eye, the correction seems perfect, which in the object glass can only be an approximation, the contrary aberrations of the lenses not having the same ratio; so that if this aberration

be perfectly corrected at any given distance from the centre, in every other it must be in some degree imperfect.

Pursuing the same comparison: in the achromatic object glass, we may conceive how much an object must appear fainter from the great quantity of light lost by reflection at the surfaces of the different lenses, there being as many primary reflections as there are surfaces; and it would be fortunate if this reflected light was totally lost. Part of it is again reflected towards the eye by the interior surfaces of the lenses, which by diluting the image formed in the focus of the object glass, makes that image appear far less bright than it would otherwise have done, producing that milky appearance so often complained of in viewing lucid objects through this sort of telescope. In the eye, the same properties that obviate this defect, serve also to correct the errors from the spherical figure, by a regular diminution of density from the centre of the crystalline outward. Every appearance shows the crystalline to consist of laminae of different densities; and if we examine the junction of different media, having a very small difference of refraction, we shall find that we may have a sensible refraction without reflection: now if the difference between the contiguous media in the eye, or the laminae in the crystalline, be very small, we shall have refraction without having reflection, and this appears to be the state of the eye; for though we have 2 surfaces of the aqueous, 2 of the crystalline, and 2 of the vitreous humour, yet we have only 1 reflected image, and that being from the anterior surface of the cornea, there can be no surface to reflect it back, and dilute an image on the retina.

This hypothesis may be put to the test, whenever accident shall furnish us with a subject having the crystalline extracted from one eye, the other remaining perfect in its natural state; at the same time we may ascertain whether the crystalline be that part of the organ which serves for viewing objects at different distances distinctly. Seeing no reflection at the surface of the crystalline might lead some persons to infer that its refractive power is very inconsiderable, but many circumstances show the contrary; yet what it really is may be readily ascertained, by having the focal length and distance of a lens from the operated eye, that enables it to see objects the most distinctly; also the focal length of a lens, and its distance from the perfect eye that enables it to see objects at the same distance as the imperfect eye: these data will be sufficient for calculating the refractive power of the crystalline with considerable precision. Again, having the spherical aberration of the different humours of the eye, and having ascertained the refractive power of the crystalline, we have data from which to determine the proportional increase of its density as it approaches the central part, on a supposition that this property corrects the aberration.

These observations of Mr. Ramsden respecting the use of the crystalline lens, I was very desirous of bringing to the proof; and while my mind was strongly impressed by them, a favourable opportunity occurred. A young man came into St. George's hospital with a cataract in the right eye: this proved to be a fair case for an operation, to which the man very cheerfully submitted, and was put under my care for that purpose. In performing the operation, the crystalline lens was very readily extracted, and the union of the wound in the cornea took place unattended by inflammation, so that the eye suffered the smallest degree of injury that can attend so severe an operation; these circumstances it is proper to mention, as they contributed to render the patient a more favourable subject for experiment. The man's name was Benjamin Clerk; he was a seafaring man, 21 years of age, and in perfect health. Both his eyes were free

from complaint till about April 11, 1793, at which time he was on a voyage home from the East Indies, a sudden mist or dimness appeared before his right eye; this increased very rapidly, and on the 18th of the same month the sight was entirely obscured. The crystalline humour was extracted on the 25th of Nov.; and 27 days after the operation the eye was so far recovered as to admit of the following observations and experiments being made on it.

In this man we had all the circumstances combined, which seemed to be required to determine how far the crystalline lens was the principal agent in adjusting the eye. The man himself was in health, young, intelligent, and his left eye perfect; the other had been an uncommonly short time in a diseased state, and appeared to be free from every other defect but the loss of the crystalline lens. He very willingly allowed me to make the following experiments on him; and remained in town, though inconvenient to himself, till they were completed; the greater part of them were instituted by Mr. Ramsden, and all of them carried through under his direction. The experiments were begun on Dec. 22, 1793, at which time the following observations were made on the imperfect eye. The eye ore the light of the day very well; but was fatigued by strong sunshine, or the glare of candle-light. In weak lights objects were not seen at all by the imperfect eye, but in strong lights they presented a faint image, which appeared at the same distance with that seen by the perfect eye, and close to it, or nearly so, but always to the left. The imperfect eye, unassisted by glasses, could see objects, but it was with a degree of indistinctness; and this indistinct vision only took place at a distance between 6 and 9 inches. With a double convex glass, the radius of one surface 1 and 1/2 inch, of the other 6 inches, the flat side towards the eye, having a focus of 2-1/4 inches, objects appeared most distinct at 4-1/2 inches, and the extremes were 2-1/4 inches, and 5-1/2 inches. The different distances were ascertained by placing one end of a foot rule against the man's forehead, and giving him the book in his own hand, desiring him to carry it to the distance at which he saw best, and afterwards to the 2 extremes of distant vision, the upper end of the book being always in contact with the rule; so that the moment he adjusted the book, the distance was read off from the scale. The accuracy with which he brought it to the same point in repeating the experiments, proved his eye to be uncommonly correct; for as he did not himself see the scale, there could be nor source of fallacy.

Making these experiments fatigued the eye considerably, and repeating them after very short intervals made the eye water, and gave a slight degree of pain; this however soon went off. In looking at objects through this glass, the image was free from any tinge of colour, unless he directed his eye towards the circumference of the glass, and then it had a considerable tinge, which evidently arose from the prismatic figure of that part of the glass. A comparative experiment was made on the perfect eye, with a glass of 15 inches focus. Objects were found in one experiment to appear most distant at 8-1/2 inches, the extremes 3 inches and 11 inches; in another; most distinct at 7 inches, the extremes as before, 3 and 11 inches.

On Dec. 29, 34 days after the operation, the following experiments were made by candle-light, about 6 o'clock in the evening. The experiment with the double convex glass was repeated, the aperture being diminished to 3/20 of an inch; objects appeared most distinct at 5 inches, the extremes 3 inches and 7-3/4 inches. The aperture was diminished to 3/40 of an inch, and vision appeared most distinct at 5 inches, the extremes at 3-1/2 inches and 7 inches. When the aperture was reduced to 1/20 of an inch, the inflexion of the rays produced the appearance of a speck, which obscured his vision. By diminishing the aperture,

spherical aberration was in a great measure corrected, and vision rendered more distinct.

A plano-convex glass of 2-7/8 inches focus, with the plane towards the eye, was now applied, and the objects were most distinct at 6 inches, but by no means well defined: the aperture was now reduced to 3/40 of an inch, and objects appeared much more distinct at 5-1/2 inches; when the glass was brought within 1/2 an inch of the eye, objects were still more distinct, and were seen at 5 inches. The eye was less affected by these than the former experiments, nor was it fatigued by the light of a candle. In strong lights a faint image was seen by the imperfect eye, and always to the left of the other. The perfect eye, with a glass of 15 inches focus, saw objects most distinctly at 8-1/2 inches, the extremes 3-1/4 inches and 11-1/4 inches. As these experiments were made with a view to determine whether the eye, when deprived of its crystalline humour, had a power of adjusting itself to different distances; that being ascertained, they were not prosecuted further, on account of the tender state of the man's eye, who went into the country as soon as they were completed.

On Nov. 4, 1794, the man returned to London, and submitted himself to be the subject of further experiments. This afforded us an opportunity of ascertaining the comparative adjustment of the 2 eyes, when by means of different glasses they were brought to see distinctly at nearly the same focal distance: an experiment we had been unable to make before for want of proper glasses. Sir Henry Englefield, who will be found to have given us his assistance in the subsequent part of his investigation, was present at this experiment, and was much astonished, as we had been in the former ones, at the accuracy with which the man's eye was adjusted to the same distance in the repeated trials that were made with it.

The perfect eye, with a glass of 6-1/2 inches focus, had distinct vision at 3 inches; the near limit was 1-7/8 inch, the distant one less than 7 inches. The imperfect eye, with a glass of 2-2/10 inches focus, with an aperture of 3/40 of an inch, had distinct vision at 2-7/8 inches, the near limit 1-7/8 inch, the distant one 7 inches. From the result of this experiment we find that the range of adjustment of the imperfect eye, when the 2 eyes were made to see at nearly the same focal distance, exceeded that of the perfect eye. These experiments were made by Mr. Ramsden, who took particular care to avoid everything that might be productive of error or deception; and repeated them several times before any conclusions were drawn from them. Several others were made on the same subject, all tending to confirm those already mentioned. It may be proper to mention a reason which suggested itself to Mr. Ramsden, why the point of distinct vision in the imperfect eye appeared to the man himself nearer than it was in reality; it arose from his judging distinctness by the legibility of the letters, which were easier to read when they subtended a greater angle, from the imperfection of his eye, than at his real point of distinct vision.

The result of these experiments convinced us that the internal power of the eye, by which it is adjusted to see at different distances, does not reside in the crystalline lens; we were also satisfied by the facts and arguments adduced in Mr. Hunter's letter on this subject, published in the last vol. of the *Phil. Trans.* that it does not arise from a change in the general form of the globe of the eye; we therefore abandoned both of these theories. It suggested itself that any change in the curve of the cornea, could it be produced, would vary the refraction of the rays, so as considerably to alter the focus of the eye; and on considering this subject, Mr. Ramsden made a rough calculation, from which it appeared, that a very small alteration in that part would vary the adjustment of the eye from parallel rays to its shortest distance of distinct

vision. This opened to us a new field of inquiry, and I endeavoured to ascertain how far the cornea admitted of such a change, and if it did, how far that change operated in producing this particular effect.

For the first of these purposes I made the following experiments in the presence of Mr. Ramsden. A portion of the cornea $\frac{1}{4}$ of an inch broad, and $\frac{11}{20}$ of an inch long, was removed from the eye of a person 40 years of age, 2 days after death, with a part of the sclerotic coat on each side attached to it. This was laid on a piece of glass immersed in water, under which was a scale divided into very minute parts, these divisions being very readily seen through the glass. One end of the cornea was made fast by fixing the sclerotic coat, and a force was applied to the other; this power was found capable of elongating the cornea $\frac{1}{20}$ part of an inch; and on removing it, the cornea recovered itself to its original length. In different trials it varied in the quantity of elongation, but in all of them it was fully $\frac{1}{11}$ part of the whole length, or diameter of the cornea.

The elasticity of the cornea being thus ascertained, encouraged me to proceed in the anatomical investigation; and I was desirous of determining more exactly than had hitherto been done, the precise insertion of the tendons of the 4 straight muscles of the eye, so as to know whether their action could be extended to the cornea or not. In dissecting these muscles to their termination, I found that they approached within $\frac{1}{8}$ of an inch of the cornea, before their tendons became attached to the sclerotic coat on which they lay; it was evident that they did not terminate at this part, but were so united as to be difficultly separated by dissection; I therefore endeavoured by gentle force to pull them asunder, as in that way the parts would separate in the direction of their fibres. In doing this, they not only admitted of separation to the edge of the cornea, but brought away a lamina of the cornea with them. I thought this would be better seen in an eye after putrefaction had begun to take place, but found that in that state it could scarcely be demonstrated; while in the recent eye the whole of the external lamina of the cornea could be brought away along with the 4 straight muscles, leaving the surface underneath uniform, but without polish, and on the same plane with the sclerotic coat, of which it was a continuation. As this was a new fact, and a very important one, showing a connection between these muscles and the cornea, I have dried the parts, and preserved them in that state, to show the mode in which the tendons of the straight muscles are lost in the cornea, giving it the appearance of a central tendon. The cornea from this investigation is proved to be composed of two laminae, the external a continuation of the tendons, or the 4 straight muscles, the other a continuation of the sclerotic coat, and the uniting medium between them is not unlike very fine cellular membrane.

When the cornea is examined at its attachment to the sclerotic coat and tendons of the straight muscles it appears to be of exactly the same thickness with those parts, but grows thicker towards the centre; this increase of thickness is principally in the external lamina; for when that is removed, the other appears equally so through its whole extent. To ascertain that the cornea is really thickest in the middle, I made a transverse section of it, and Mr. Ramsden, with several other gentlemen, examined the cut edge through a magnifying glass, and all of them were satisfied with the fact of the central part being evidently thicker than that which was nearer to the circumference. In stretching the cornea, the central part yields most readily to the power applied; this is so much the case, that if the cut edge of the cornea be examined while it is several times drawn out and allowed to contract again, the change in the centre will be found the most distinct; the principal elasticity appearing to reside in that part.

Before these experiments were made on the cornea, Mr. Ramsden had promised that he would contrive an instrument by which the cornea might be examined, while the eye was adapting itself to different distances; so as to enable us to decide whether any change took place at these times in its external figure. When I state to the R.S. that 7 months elapsed before the apparatus for this experiment was completed, they will not attribute it to a want of solicitude on my part, or a want of attention in Mr. Ramsden; but to delays which must necessarily occur to an artist so extensively employed in business, and at the same time so ready to engage both from inclination, and the urgent requests of his friends, in promoting philosophical inquiries.

On July 31, 1794, we were enabled to begin our experiments, for which the following apparatus was constructed. A thick board was fixed to a strong upright support, directly opposite to the window of Mr. Ramsden's front room on the first floor, which looks up Sackville-street, at the distance of 1 foot from the window. In this board was a square hole, large enough to admit a person's face, the forehead and chin resting against the upper and lower bars, and the cheek against either of the sides, so that when the face was protruded, the head was steadily fixed by resting on 3 sides, and in this position the left eye projected beyond the outer surface of the board. On the outside of the board, or that next to the window, on the square hole was fixed a microscope, so placed as to take into its field the lateral part of the front of the cornea, which projects beyond the eyelids. The microscope had not only a movement directly forwards, but by means of endless screws, had also a vertical and horizontal motion, without which the experiments could not have been made with any degree of precision. From the upper part of the square hole a horizontal brass beam projected towards the window, with joints, by which it could be lengthened or shortened; and at the end of this a brass plate was suspended, which admitted of being raised or depressed, so as to bring a small hole that had been drilled through it directly opposite to the eye.

With this apparatus we began our experiments; and I consider it as a fortunate circumstance that Sir Henry Englefield arrived in town the night before they were made; he very cheerfully gave his assistance the moment I made the request. Sir Henry, from his practical knowledge of mathematical instruments, and the habit of making observations with them, rendered us very material assistance in the course of our experiments, and I feel myself obliged to him for remaining in town till they were completed. To Mr. Ramsden and myself it was a particular satisfaction to have an evidence who had no presupposed opinion, therefore impartial; whose knowledge of the subject enabled him to form a judgement of the results, and to correct any error we might fall into in conducting the experiments. This circumstance will also give to the experiments an additional claim on the notice of the R. S.

The first experiment was made at 3 o'clock, at which were present Sir Henry Englefield, Mr. Ramsden, and myself. It required some time, and considerable ability, in which I claim no part, to adjust the microscope, and bring the cornea into its field: when this was done, the appearances were so different from what were expected, that we had a difficulty in recognizing the object, all that could be seen was 4 curved lines, but even these were rendered confused by reflections from the cross bars of the sash of the window. On throwing up the sash, the curved lines became very distinct, and that which appeared the inner one in the microscope, was ascertained to be the convex projecting surface of the cornea. This being determined, the person whose eye was the object of the experiment was desired to look at the

corner of a chimney at the upper end of Sackville-street, a distance of 235 yards, through the hole in the brass plate, and afterwards to look at the edge of the small hole itself, which was only 6 inches from the eye. In doing this several times, the curved lines were seen to separate from each other; and the microscope required being withdrawn from the object whenever the person's eye was adjusted to the near distance; but the very reverse took place when it was fixed on the distant one.

In making these experiments, the least motion of the head carried the cornea out of the field of the microscope; it was therefore necessary that the 2 objects should be exactly in the same line respecting the eye, and that the person should remain silent. When he complied with any request which had been made, he signified by touching the knee of the observer with his hand, that he had done so. This experiment was made on the eyes of all present, and the same appearances were uniformly observed; and after several trials we became so familiar with the appearances, that the observer only required information of the adjustment having been changed, to enable him to tell which of the objects the eye was fixed on.

August the 1st, about 4 o'clock, these experiments were repeated, and after several attempts were made, without success, to explain the cause of the curved lines, we found it necessary to shade a part of the window, to take off the glare of light which fatigued the eye, and rendered it unsteady; this made the curved lines less distinct; and when the whole window was shaded they disappeared altogether, leaving a very distinct view of the whole thickness of the cornea, with a well defined line formed by its anterior projecting surface. This discovery proved the curved lines to be reflections from the sides of the window on the cornea, but as it was not made till 6 o'clock, we were obliged to postpone any further observations on it.

August the 3d at 7 o'clock in the morning, Mr. Ramsden and myself resumed our experiments, Sir Henry Englefield being unable to attend at that hour. The eye of the person under observation was shaded from the light by shutting the half of the window-shutter directly before it, and to direct the sight to pass through it, a hole was bored in the shutter; the other half of the shutter was turned back, so as to take off the side light, only letting in enough to illuminate the cornea; in this state the cornea was very distinctly seen, and the former experiments were repeated on it, with a micrometer wire in the focus of the eye-glass, so placed as accurately to oppose the anterior edge of the cornea. The motion of the cornea became now perfectly distinct; its surface remained in a line with the wire when the eye was adjusted to the distant object, but projected considerably beyond it when adapted to the near one; and the space through which it moved was so great as readily to be measured by magnifying the divisions on a scale, and comparing them; in this way we estimated it at the 800 part of an inch, a space distinctly seen in a microscope magnifying 30 times. It may not be improper, for the sake of accuracy, to mention that the hole made in the window-shutter did not admit of seeing up Sackville-street, so that the distant object was now only at 90 feet, which is rather less than is necessary for parallel rays; a circumstance, so far as it can be considered, in favour of the experiment, as a more distant object must have increased the effect on the cornea. Having satisfied ourselves fully respecting the result of this experiment, we desisted from further trials.

At 12 o'clock of the same day, we prevailed on Sir Henry Englefield to make the experiment on my eye, without giving him any information on the observations that had been made in the morning. He was very

much struck with the distinctness of the cornea; and told me without difficulty the different objects to which my eye was adjusted, and was as fully satisfied as either Mr. Ramsden or myself with the result of the experiment. Mr. Ramsden now made the same experiment on Sir Henry's eye, but was unable to retain it in the field of the microscope; the motion of the cornea was always in one direction, and very irregular; after repeated trials, equally unsatisfactory, the eye became so fatigued that he was obliged to desist.

August th 4th, Mr. Ramsden repeated the experiment on Sir Henry's eye, to ascertain if possible the cause of his former want of success, and found the same circumstances again take place; the curve of the cornea moved always in the same direction, never returning to the wire. This could not be accounted for, till it was accidentally discovered to arise from the motion of his hand in touching the kneww of the observer, for when that was omitted, the experiment was followed by the same results as those made by the rest of the company. I have been more particular in mentioning this circumstance, as it shows that the most trifling things may interfere with the result of the experiment, and that it required a considerable degree of nicety and management in adjusting the instrument, without which the experiment could not have been made.

August the 28th, the former experiments were repeated by Sir Henry Englefield, Mr. Ramsden, and myself, on the eye of a young lad, and the result was similar to the others, the motion of the cornea was uncommonly distinct. Sir Henry now became the subject of the experiment, and changed the adjustment of his eye from one distance to another in a very irregular manner, without giving the smallest information, with a view to embarrass Mr. Ramsden who was the observer, but without effect, for Mr. Ramsden was able to tell every change in distance he had made, without a single mistake; this exceeded our expectation, and appeared to us so satisfactory that we required no further proofs of the truth of our former observations. Before we concluded our experiments, every mode that could be devised was put in practice to see how far there might be any deception; the eye was moved on its axis, and in different directions, but these motions did not give at all similar appearances to those seen in the adjusting of the eye to different distances.

From the different experiments which I have had the honour to lay before the R. S., I shall consider the following facts to have been ascertained. 1st, That the eye has a power of adjusting itself to different distances when deprived of the crystalline lens; and therefore the fibrous and laminated structure of that lens is not intended to alter its form, but to prevent reflections in the passage of the rays through the surfaces of media of different densities, and to correct spherical aberration. 2d, That the cornea is made up of laminae; that it is elastic, and when stretched, is capable of being elongated $\frac{1}{11}$ part of its diameter, contracting to its former length immediately on being left to itself. 3d, that the tendons of the 4 straight muscles of the eye are continued on to the edge of the cornea, and terminate, or are inserted, in its external lamina: their action will therefore extend to the edge of the cornea. 4th, That in changing the focus of the eye from seeing with parallel rays to a near distance, there is a visible alteration produced in the figure of the cornea, rendering it more convex; and when the eye is again adapted to parallel rays, the alteration by which the cornea is brought back to its former state is equally visible.

Having supported these facts by the evidence of anatomical structure, and absolute demonstration, I shall consider them to be established; and make some observations on the muscular and elastic power by which so very curious an effect as the adjustment of the eye is produced. The 4 straight muscles of the eye are attached to the bottom of the bony orbit near the foramen opticum; they become broader as they pass forward, and when arrived at the anterior part of the eye-ball, are insensibly changed for tendons; these adhere to the sclerotic coat, and terminate in the external lamina of the cornea, which appears to be a continuation of them.

When we consider the situation of these muscles, it is evident that their action will produce 3 very different effects on the eye, according to circumstances. When they act separately, they will move the eye in different directions; when together, with only a small quantity of contraction, they will steady the eyeball; and when this is increased they will compress the lateral and posterior parts of the eye. This compression of the eye will force the aqueous humour forwards against the centre of the cornea, while the circumference is steadied by the muscles, so that the radius of curvature of the cornea will be rendered shorter, and its distance from the retina increased. That the eye-ball cannot be made to recede in the orbit by any of these actions, is sufficiently proved by its not having done so in any of the experiments. These muscles are uncommonly large, and come much more forward than appears necessary for the purposes generally assigned to them; but when applied to so important an office as that we have just stated, their size, and anterior insertion, are easily explained.

It may be imagined that I have allotted to these muscles a greater variety of uses than is compatible with the simplicity of the general laws of the animal economy: but to prove this not to be the case, I shall only bring the biceps flexor cubiti as an instance of a similar kind. That muscle is attached to the scapula by both its heads, one of which passes through the joint of the shoulder, they afterwards unite, and their common tendon is inserted into the radius; when the muscle contracts, the first effect will be to steady the joint of the shoulder; if the contraction be increased, it will rotate the radius, and if still more increased, bend the fore-arm.

There are many instances in animal bodies of elasticity being substituted for muscular action, but this in the eye is by much the most beautiful of those applications. In the vascular system the arteries are composed of muscular fibres, and an elastic substance; in the natural easy state of the circulation, the reaction in the larger vessels is principally the effect of elasticity; but when increased, it is the effect of muscular contraction. The claws of the lion are drawn up, and supported from the ground, by means of elastic ligaments; but they are brought down for use, which is an action not so often required, by muscles. In the adjustment of the eye it is the same; the state fitted for parallel rays is the effect of elasticity, but that for nearer distances, which is less frequently wanted, is the effect of muscular action. In these different instances, the intention is uniformly to avoid the expence of muscular action whenever the effect can be produced in any other way, as muscular actions consume a considerable quantity of blood, which is the nourishment of the body. That the adjusting the eye to near distances is the effect of an action, or exertion, was very evident to every gentleman concerned in these experiments. In changing the focus of our eyes, we were much astonished, particularly Sir Henry Englefield, at the exertion required to adjust the eye to the near distances, and the facility with which it was adapted to distant ones; the first was a strain on the eye, the 2d appeared a relief to it. When the eye was intent on the near object,

it required the attention to be constantly kept up, or the object became indistinct, and if we looked at it beyond a certain time, the eye was so much fatigued as to use it at intervals. This corresponds with other muscular actions, for whenever muscles are kept long in one state they begin to vibrate involuntarily.

These circumstances explain what may be called a coup d'oeil, or the distinctness with which an object is seen when the eye is first fixed on it. This arises from the nice adjustment produced by the muscles when first thrown into action, which they cannot keep up, being unable to remain long in the same state; nor can they, after having been used for any time, return to this adjustment with the same exactness.

The change that takes place in the eye at an advanced period of life, by which it loses its adjustment to very near, and at very distant objects, does not arise from any defect in the muscles, as might at first be imagined, since that would not account for the eye being unable to see with parallel rays; nor is there any obvious reason why these muscles should lose their powers, while others, which are not apparently so strong, if we may judge by their effects, retain their full action long after the eye has undergone this change. This defect in the eye, I am led to believe, is brought on by the cornea losing its elasticity as we advance in life, neither contracting nor being elongated to its usual extent, but remaining in a middle state. That elastic substances in the body do undergo such a change, may be well illustrated in the vascular system. The aorta is composed almost entirely of elastic substance, and there is probably no part of the body, at an advanced age, which is so often found to have lost its natural action; it appears to undergo change from age alone, becoming inelastic, and then taking on diseases of different kinds, as being ossified, or becoming aneurismal; but in neither of these diseases is it found to be contracted, though often the reverse, and when disease has not supervened, the artery more commonly remains in the middle state.

The cornea, having similar properties must be liable to a similar change; but its action being less constant, and the power which to resist being weaker, the change will be probably more gradual and less in degree, but sufficient to account for the alteration we find in the focus of the eyes of old people. There are many other circumstances respecting vision, and many which occur in disease, that may be explained by a knowledge of these facts; but as this lecture is only intended to establish the facts themselves, in doing which I have already taken up too much of the time of the R. S., I shall at some future period consider their application to the phenomena of vision in health and disease.

Fig. 10, p. 5, shows portions of the four straight muscles of the eye, with their tendons insensibly lost in the external lamina of the cornea, stretched out and dried. The tendons become broader as they approach the cornea, and form a circle of which the cornea appears to be a continuation. 

The (1795) Croonian Lecture on Muscular Motion.

By Everard Home, Esq. F. R. S. From *Philosophical Transactions of the Royal Society of London* vol. 86 (1796), pp. 1ff.

In the Croonian Lecture which I had the honour of laying before the R. S. last year, I endeavored to prove, that the adjustment of the eye to different distances could take place independent of the crystalline lens; and that when this was the case, it appeared to arise from a change in the curvature of the cornea. I propose in the present lecture to prosecute the inquiry; and it will be found in this, as well as in the former, that I have received the most essential assistance from Mr. Ramsden, who continues to interest himself in the investigation, and has made all the optical experiments. As this was a new mode of explaining the adjustment of the eye, and differed from the theories that have been previously formed on the subject, it was thought right to consider it with caution, to pay attention to all the objections that could be made to it, and to put it to the test of such experiments as appeared likely to refute or confirm our former observations.

It readily suggested itself, that if the convexity of the cornea was increased to a certain degree, it could be measured by means of an image reflected from its surface, and viewed in an achromatic microscope, with a divided eye-glass micrometer. To ascertain whether the quantity of increase of the convexity of the cornea, in the adjustment of the eye, could in this way be ascertained, the following experiments were contrived, and made by Mr. Ramsden. Our former experiments had sufficiently proved the unsteadiness of the human eye; the first trials on the present occasion were therefore made on convex mirrors, as these artificial corneas could be more readily managed, and such previous experiments would enable us to apply the same instruments with more facility to the eye itself.

Two convex mirrors, one $\frac{4}{10}$ of an inch focus [98.43 D], the other $\frac{5}{10}$ [78.74 D], had their flat surfaces made rough, and blacked, to prevent an image being seen from both surfaces, which was found to be the case when this precaution was omitted. One of these mirrors was struck on a piece of wood directly opposite to a window, at 12 feet distance from it; a board 3 feet long, and 6 inches broad, was placed perpendicularly against the sash of the window, and its image reflected from the mirror on the object-glass of an achromatic microscope, with a divided eye-glass micrometer. The 2 images were separated by means of the divided eye-glass, till their surface of contact, which appears like a black line, was rendered as small as possible. When this effect was produced on the images from the mirror of $\frac{4}{10}$ of an inch focus [98.43 D], that mirror was removed, and the other put into its place; the contact of the 2 images, which before appeared like a line, had now acquired considerable breadth; corresponding exactly to the

difference between the convexities of the mirrors.

Having in this way made trial of the instruments, and arranged all the necessary circumstances, the head of a person was so placed as to bring the eye into the same situation as the mirror, and made steady by the apparatus described in our former experiments. Under these circumstances the image reflected from the cornea was measured by the micrometer. Mr. Ramsden made an experiment with this instrument on my eye. In the first trials, when the eye was fresh, there was a perceptible change in the micrometer, but extremely small; this was not however seen afterwards, and the eye very soon became so much fatigued that it was necessary to desist. He found that every time the eye adapted itself to different distances, it was necessary to move the object-glass of the microscope farther from, or nearer to, the cornea.

This experiment was repeated on 4 different days; and in each experiment, on the first trial, the result was a change in the micrometer, but in all the subsequent trials it could not be detected. We were induced to conclude, that the effect on the micrometer might arise from the head being moved forwards, as we found, in making experiments with the mirror, that this effect could be produced by such motion; but had it arisen from that cause, it should more frequently have occurred, and rather after the head and eye were tired, than on the first trials. It was supposed to arise from the action of the muscles of the head, but that should have produced a contrary appearance. The effect produced on the micrometer therefore did not seem to depend on external circumstances, but to arise from a change in the cornea; it was however too small to admit of any conclusions being drawn from it. The same experiment was made on several young persons; but we found it necessary, that whoever was the subject of the experiment should understand perfectly what was meant to be done, otherwise the conclusions could not be depended on; for if the eye does not see the near object with a very defined outline, it is not accurately adjusted to it; and the length of time they keep their eye on the near object without making any complaint of being fatigued, was greater, we knew from our own observation, than it was possible to do it, had the object been seen with the necessary degree of distinctness.

Finding from these experiments, that the change in the convexity of the cornea was not to be seen distinctly in the micrometer, it became an object to ascertain the degree of change which could in this way be distinctly determined. For this purpose 2 mirrors were ground, and prepared in the same way as those used in the preceding experiment; their radii were exactly ascertained by measuring the tools in which they were finished off; the one was $\frac{4}{10}$ of an inch focus [98.43 D], the other $\frac{408}{1000}$ [96.50 D], the difference between the size of the images reflected from their surface was just visible in the micrometer; and from their remaining fixed, the experiment could be made with every advantage; but it did not appear probable that the same difference would have been visible had the mirror not been perfectly at rest. A smaller change could not therefore be detected in the eye; and when we consider the disadvantages under which an experiment of this nature must be made on the human eye, from the unsteadiness of that organ, the short time it remains adjusted (a part of which is lost in bringing it within the focus of the microscope), and also from the motions of the head; it is not unreasonable to suppose that a change might take place in the cornea, to the same extent, without being distinctly seen.

To give an idea of the short time that a part can remain nicely adjusted by muscular action, I shall point out an experiment which any one may make on himself: let him take a glass spirit level, and rest one end

of it on a table, supporting the other with his hand, and endeavour to keep the air bubble in the middle; if the hand is very steady the bubble may be kept nearly in its place, but not exactly so; it will undulate, its motion corresponding with the actions of the muscles; making up for want of steadiness by short motions in contrary directions.

From these experiments the change in the curvature of the cornea could not be more than $1/125$ part of an inch [0.20 mm], as any greater quantity would probably have been distinctly seen in the micrometer; this however is still more than was ascertained by our former experiments, which made it to exceed $1/800$ part of an inch [0.03 mm]. This change in the cornea, on the first view of the subject, appeared sufficient to account for the adjustment of the eye; and when the lens is removed it probably may be sufficient; but the refractions at the cornea are so much changed by those at the lens, as considerably to lessen their effect in fitting the eye for seeing near objects, and make this small increase of convexity inadequate to such an effect. Finding this to be the case, it became necessary to examine the eye with attention, to see in what way the full effect was most likely to be produced. For this purpose the following experiments were made on the human eye, to determine whether the axis of vision could be elongated by any uniform pressure applied to its coats.

The experiments were made in the following manner: an eye of a dead subject was carefully removed from the socket, before any change could be produced in consequence of death, and its different diameters were measured by a pair of caliper compasses. As soon as these were determined, a hole was made in the centre of the optic nerve, and a pipe fixed into it, through which air could be thrown into the cavity of the eye, so as to distend its coats. While distended in a moderate degree, by compressing with the hand a small bladder, containing air and quicksilver, attached to the pipe, the same diameters were measured again, and compared with those which were taken while in the natural state. These experiments were made by Mr. Muttletbury and Mr. Williams, two very intelligent and dilligent students in surgery, who were filling situations that gave opportunity of making such experiments. They measured the diameters in these 2 states, and marked them on paper, without ascertaining their difference, so that there could be no fallacy in the measurement from any pre-conceived opinion; and I have every reason to believe there was none from inattention.

A = The eye of a boy 6 years old, 45 minutes after death

B = The eye of a man 25 years old, 1 hour after death

B = The eye of a man 50 years old, 20 minutes after death

Measurements given in 20th parts of an inch.

	Transverse diameter	Axis from optic nerve	Axis of vision
A Natural state	$17-1/2$	$17-1/2$	$17-1/2$
Distended state	$17-1/4+$	$17-1/4+$	18
B Natural state	$17-3/4$	$17-3/4$	17

	Distended state	17-1/2	17-1/2	17-1/2
C	Natural state	19	19	18-1/2
	Distended state	19	19	18-1/2

Measurements converted into mm.

		Transverse diameter	Axis from optic nerve	Axis of vision
A	Natural state	22.23	22.23	22.23
	Distended state	21.90+	21.90+	22.86
B	Natural state	22.02	22.02	21.59
	Distended state	22.23	22.23	22.23
C	Natural state	24.13	24.13	23.49
	Distended state	24.13	24.13	23.49

From these experiments it appears, that the diameters of the eye do not always bear the same proportion; sometimes the transverse diameter is the longest, in other eyes it is of the same length as the axis of vision; but when the coats are distended, the transverse diameter is diminished, and the axis of vision is lengthened. This change, however, does not take place at all ages, for at 50 it was not met with.

In those experiments the pressure was made in the most unfavourable way for producing the greatest degree of elongation in the axis of vision; it was however the least exceptionable mode for ascertaining that such an effect could take place; when the pressure is made laterally and from without, the elongation must be still greater; and the action of the straight muscles is the most advantageous that could be imagined for that purpose. This lateral pressure will not only elongate the eye, and increase the convexity of the cornea, but it will produce an effect on the crystalline lens and ciliary processes, pushing them forward in the same proportion as the cornea is stretched. This is necessary for two reasons; viz. to preserve the cavity containing the aqueous humour always of the same size, and to keep the cornea and lens at the same distance from each other. The ciliary processes, as they form a complete septum between the vitreous and aqueous humours, must be moved forward, together with the lens, when the cornea is rendered more convex, and when the cornea recovers itself they are thrown back into their former situation. In order to effect this with the nicety that is required, the ciliary processes are probably possessed of a muscular power.

That the ciliary processes are muscular is a very generally received opinion, and in the course of this lecture I shall adduce some facts in favour of it; they will also tend to confirm the opinion of these processes being a sling, in which the lens is suspended, and rendered capable of a small degree of motion. The result of this inquiry, which has not been confined to the support of any particular theory,

but carried on with the sole view of discovering the truth, appears to be, that the adjustment of the eye is produce by 3 different changes in that organ; an increase of curvature in the cornea, an elongation of the axis of vision, and a motion of the crystalline lens. These changes in a great measure depend on the contraction of the 4 straight muscles of the eye. Mr. Ramsden has made a computation, by which the degree of adjustment produced by each of these changes may be ascertained. This he has promised to render more correct; and also to institute a series of experiments by which the effects of the motion of the lens may be more accurately determined. From Mr. Ramsden's computation, the increase of curvature of the cornea appears capable of producing $1/3$ of the effect; and the change of place of the lens, and elongation of the axis of vision, sufficiently account for the other $2/3$ of the quantity of adjustment necessary to make up the whole.

Having explained the mode by which the axis of vision can be elongated, and the convexity of the cornea increased, in the human eye, for the purpose of its adjustment, I was desirous of applying these observations to the eyes of other animals, that I might see whether their different structures would admit of the necessary changes, for producing an adjustment to different distances in the same way. As many animals are known to have their vision distinct at very different distances, it appeared that much information might be gained by examining the structure of the eyes of those whose range of vision varies most from that of the human eye. Quadrupeds in general must have their eyes fitted to see very near objects, as many of them collect their food with their mouths, in which action the objects are brought very close to the eye. Birds are under the same circumstances in a still greater degree with respect to their food; but from their mode of life, they also require the power of seeing objects at a great distance. Fishes, from the nature of the medium in which they live, must have some other mode of adjusting the eye, than that of a change in the cornea, as that substance is possessed of the same refractive power with the surrounding fluid.

To avoid confusion in so extensive a field of inquiry, I shall separately consider the peculiarities in the eyes of these different classes of animals, so far as they appear to be concerned in producing the adjustment to different distances. Quadrupeds have 3 modes of procuring their food; one by their fore-paws only, which they use like hands, as all the monkey tribe; the 2d, by their fore-paws and mouths, as the lion, and cat tribe; the 3d, by the mouth only, as all ruminating animals. These 3 different modes require the food being brought to different distances from the eye; and it is curious, that the muscles of the eye are different in all the 3 tribes. In the monkey tribe, the muscles of the eye are exactly the same as in the human. In the lion tribe, they are double in number, and the 4 intermediate muscles are lost in the sclerotic coat, at a greater distance from the cornea than the others. In the ruminating tribe, they are double in number, and the 4 intermediate muscles are lost in the sclerotic coat, at a greater distance from the cornea than the others. In the ruminating tribe, there are 4 muscles, as in the human eye; but there is also a muscle surrounding the eye-ball, attached to the bottom of the orbit, round the hole through which the optic nerve passes, and lost on the sclerotic coat immediately before the broadest diameter of the globe of the eye; the upper portion of this muscle is rather the longest, but not to the axis of the eye from the entrance of the optic nerve.

In quadrupeds in general, the ball of the eye is broader in proportion to its depth, than in the human subject; in the bull the proportion is $1-5/8$ inch to $1-3/8$. The cornea is larger and more prominent; its real

thickness is hardly to be determined, since, as well as that of the human eye, it readily imbibes moisture immediately after death. When dried, it is thinner than the sclerotic coat in the same state. In ruminating animals, it appears externally of an oval form; it is not however really so, the cornea itself being circular, as in other animals; but a portion of it is rendered opaque, by a membrane which covers its external surface, and produces an oval appearance. This circular form of cornea is necessary, that when it is stretched it may form a regular curve. The ciliary processes, as in the human eye, are connected with the choroide coat; but they are larger, and are united at their origin with the iris. This structure of the eye in quadrupeds, so far as it differs from that of the human eye, appears calculated to increase the power of adjusting it to see near objects, and from the mode of life which these animals pursue, such additional powers appear necessary to enable them with ease to procure their food.

The (1801) Croonian Lecture. On the Power of the Eye to adjust itself to different Distances, when deprived of the Crystalline Lens.

By Everard Home, Esq. F. R. S., Read November 5, 1801 to the Royal Society of London. From *Philosophical Transactions of the Royal Society of London*, vol. 92 (1802), pp. 1-11.

It is intended, on the present occasion, to state some facts and observations, in support of an opinion advanced in a former lecture, that the adjustment of the eye to see objects at different distances, does not depend upon any internal changes in the crystalline lens.

The first of the experiments which will be stated, was made with the assistance of the late Mr. Ramsden; and, had not the death of that valuable member of this Society deprived me of his further aid, the following observations would undoubtedly have been more deserving the attention of my learned audience.

It is impossible for me to mention Mr. Ramsden, from whom I have received so much assistance in every pursuit connected with optics and mathematics, in which I have been engaged, without availing myself of this opportunity of paying that tribute of gratitude to his memory, which feelings of delicacy prevented me from offering to him while alive. It is unnecessary ere to mention his genius, his merits, or his exertions for the promotion of science; these are equally well known to every member present, as to myself. It is only my individual obligations, in the prosecution of inquiries connected with the objects of this learned Society, that are meant to be taken notice of.

To his friendly and zealous assistance I am indebted for the information which was necessary to enable me to prosecute investigations upon the subject of vision; and, without such assistance, I should have shrunk from the enquiry. It is also to his early friendship, and his readiness to communicate to me his knowledge, that I look back, as among the sources of my early exertions, and love of philosophical pursuits.

In the year 1794, I laid before this learned Society some experiments, suggested and made by Mr. Ramsden, upon the comparative powers of adjustment of the eye, when in a perfect state, and when

deprived of the crystalline lens. From the result of these experiments it appeared, that the removal of the lens did not deprive the eye of the power of seeing distinctly at different distances. As the person upon whom the experiments were tried did not see very distinctly, without a substitute for the lens, in making them, a double convex glass, of 2-1/4 inches focus, was placed before his eye; and, to render the image distinct, by correcting the spherical aberrations, the aperture was diminished to 3/20ths of an inch; a less degree of diminution not answering that purpose.

The subject of these experiments was Benjamin Clerk, twenty-one years of age; one of his eyes was in a very perfect state, and the other without defect, except what arose from the removal of the lens: and the results appeared to be satisfactory in deciding, that the eye, when deprived of the crystalline lens, retains a power of adjustment.

Opportunities of instituting experiments of this kind very rarely occur; the patients who have had their lenses extracted, either not seeing sufficiently well, or being too much advanced in life to be fit subjects for that purpose; but, in the year 1798, the following case came under my care, which enabled me to make some further observations, in confirmation of the former experiments.

Henry Miles, a carpenter, at Westborough Green in Sussex, fifty years of age, applied, in the month of August, 1798, at St. George's Hospital, to be admitted as a patient, on account of blindness, from having a cataract in each eye; and was received under my care. Both the cataracts were extracted; and the eyes recovered from the effects of the operation, without suffering from inflammation. The right eye had the power of seeing objects with unusual distinctness; but the left was less perfect, the iris having been slightly torn, by the lens being too big to pass through the aperture, without injuring the membrane.

As soon as this man's eyes had recovered, I requested Mr. Ramsden to repeat some of the former experiments, on his right eye; which he readily agreed to do. Before the experiments were made, upon trying what was his power of vision with the naked eye, we were agreeably surprised to find that he saw so distinctly, as to admit of our ascertaining, without the aid of glasses, what were the ranges of his eye's adjustment.

A piece of pasteboard, with a letter of a moderate size, as an object upon it, was put into his hands; as he could not read, the page of a book might have confused him: he was directed to vary the distance of the pasteboard from his eye, till he had ascertained the nearest and most distant situations, in which the object appeared distinct; these distances, by measurement, were 7 inches, and 18 inches. In repeating this experiment several different times, he brought the object very correctly to the same situations.

This result convinced Mr. Ramsden, that the eye possessed the power of varying its adjustment; and he did not think any more complex experiments would be nearly so satisfactory; consequently, no others were made, and the man was allowed to go into the country.

It was intended to make him a present of a pair of spectacles, allowing him to choose those best adapted to his eye; but his sight was so very good, that we entirely forgot it, till some time after he was gone.

These experiments confirmed the former ones so very strongly, and from their simplicity were so much less liable to error, that Mr. Ramsden and myself considered the object of our inquiry completely attained; the reason for not, at the time, laying them before this learned Society was, that they established no new fact, and the former ones did not appear to require their support.

This inquiry, always regarded as highly important by physiologists, has continued to engage their attention; and, in the Bakerian Lecture for last year, Dr. Young has advanced some experiments to prove, that the adjustment of the eye to different distances, depends upon the crystalline lens: he considers the results of the experiments made by Mr. Ramsden, upon Benjamin Clerk's eyes, as inconclusive; and the phenomena met with, as arising from the smallness of the aperture, and not from any power of adjustment in the eye. Dr. Young, therefore, with a view to obviate all possibility of deception in future, constructed an optometer, upon the principle of that of Dr. Porterfield. In this instrument, when applied to presbyopic eyes, the eye, by looking along a line through a small convex lens, before which is placed a card with two narrow slits in it, near enough to each other to be within the limits of the pupil, will see the line as two lines, crossing each other at the point of perfect vision; and every eye that has the power of adjustment, will make the lines cross in different places, when adjusted to different distances.

With this instrument, Dr. Young made experiments upon several eyes which had been deprived of the crystalline lens; and with all of them found, that the crossing of the lines was seen only at one point; he therefore concludes, that the power of adjustment was lost.

These experiments of Dr. Young led me to reconsider the subject; and it was matter of regret that Benjamin Clerk was not in this country, as making a trial with the optometer on his eye, would have determined, in the most satisfactory manner, whether there had been a fallacy in the former experiments.

This not being in my power, I made inquiry after Henry Miles, upon whom the second experiments were tried; and I had the pleasure to hear, that he was in good health, and that his eyes continued to have very distinct vision, so much so, that he never had occasion to make use of any glasses, from the time the operation had been performed.

With the view of making some experiments on this man's eyes, with Dr. Young's optometer, I procured that instrument from Mr. Cary, the optician, made exactly in the same manner as that which had been executed under Dr. Young's direction. I first, however, tried the experiments upon my own eye; but had the mortification to find myself unable to make the lines cross in two different situations. This led me to try the eyes of several of my friends; who were equally unable to make the lines cross any where, except at one point. Young people, indeed all those under thirty years of age, were capable of varying the place of intersection; but none who were above forty, could produce any change in it.

As I could not doubt of my own eye having the power of varying its adjustment, I was led to believe that the instrument required some address in the management, which I had not acquired; and therefore despaired of making Henry Miles sufficiently master of it, to do justice to my views.

To obviate these difficulties, I adapted the optometer, without the lens, to presbyopic eyes, by making a line 4 feet long, upon strong paper, divided into inches, and having the same slits to look through as in the other. This instrument, and Dr. Young's, I put into the hands of my friend Sir Henry Englefield, with a request that he would examine them, and, when he had become perfectly master of them, and of the best mode of using them, that he would assist me in making experiments with them; for, as he was more in the habit of changing the focus of his eye, in using optical instruments, he would more readily detect the circumstance which prevented me from succeeding in the experiment.

After several trials with this optometer, and seeing its defects, Sir Henry Englefield improved it, by having the paper pasted upon a strong board, 4 feet long, which rendered the surface free from the slightest inequalities; and, instead of a line marked with ink, a thread of black silk was stretched along the middle of the board. With this instrument, he found that his eye could make the lines cross at two different points, at several inches distance from each other. The readiest mode of making the experiment succeed, was first fixing his eye upon some near object, held above and a little on one side of the silk thread, and, when the focus of his eye was adapted to that distance, then to look at the thread; afterwards to look at some distant object, and when that had become very distinct, again to look at the thread. Upon trying the instrument with my own eye, in this way, I found the crossing of the lines changed in its situation, with every change of adjustment; and, after being accustomed to make this experiment, I was enabled to produce a similar change in the optometer with the lens, but by no means in so satisfactory a manner, nor did it last more than an instant; my eye probably not being so well fitted as many others, for experiments of this kind.

The optometer without the lens was hence admitted to be the most easily managed, by the eye of a person unaccustomed to such experiments, and therefore it was determined to make use of it in the trials upon Henry Miles's eye; which we were enabled to do, as his vision was sufficiently distinct without the aid of glasses, and as, from never having used them, he saw much better with his naked eye.

The following experiments were made with the optometer without the lens, on the 27th of August, 1801.

The first trials were upon Sir Henry Englefield's eye; which, being most familiar with the use of the instrument, became a standard with which the others might be compared.

Sir Henry Englefield's eye made the lines to intersect each other at 12-1/4 inches, as the near distance; and at 28-1/2 inches, as the furthest distance. The experiment was repeated several different times, and the results were very nearly the same.

My own eye made the lines intersect at 12-1/2 inches, as the near distance; and at 29-1/2 inches, as the furthest distance.

A man servant of Sir Henry Englefield's, twenty-five years of age, made the lines intersect at 12 inches, and at 31-1/2 inches.

Henry Miles, fifty years of age, whose eye had been deprived of the crystalline lens for three years, made the lines intersect at 8-3/10 inches, as the near distance; and at 13-3/10, as the furthest distance.

This experiment was repeated two different times in the forenoon, with the same result, and again in the afternoon, without there being any considerable variation; but, upon trying it again, after the eye had been fatigued, he was unable to make the lines cross nearer than 11-2/8 inches, although he could make them cross at 13-3/10 inches; so that adjusting the eye to a near distance, was more difficult after it had been much used, than before.

Henry Miles was unable, in the optometer with the lens, to produce any change in the crossing of the lines, nor did he see them cross with sufficient distinctness to make us consider it a fair experiment.

The following experiment was made upon Miles's eye, at the suggestion of Sir Henry Englefield, with a view to ascertain in another though less decisive way, whether any change took place in it, when directed from a near object to a more distant one.

A piece of pasteboard in which a black circle, about 1/4 of an inch in diameter, with a dot in the centre, had been described near to its edge, was placed perpendicularly to the horizon, at 5 inches distance from the eye; another piece of pasteboard, with a circle and dot in it, was placed at the distance of 18 inches; the farthest circle was made a little larger than the other, that it might appear equally distinct at the greater distance. When the eye was directed towards these two objects, they appeared upon the same level; and the circumference of the circles, had they been projected on the same perpendicular plane, would have been nearly in contact.

Miles was placed opposite these objects, with his head made steady, and prevented him from moving: he was then told to look at one, till it became very distinct; and, when he had done so, this was removed, and he was directed to look at the other, which did not immediately appear to him with the same distinctness. This was equally the case, whether he looked from the near one to the distant one, or the reverse: the eye did not see the object to which it was so suddenly directed, with the same defined outline as that from which it had been withdrawn.

This man sees best in a strong light; and it was in that light all the experiments were made: he can see very well in any degree of daylight; but his eyes are much fatigued by candlelight. Upon examining the eye attentively, the pupil was rather larger than in perfect eyes; the iris was in a very perfect state; and the cicatrix of the wound, in the inferior part of the cornea, was scarcely visible.

The sight being so good, without the aid of glasses, is not common; and, had not the lenses been extracted in a public hospital, before a number of spectators, some doubts might be entertained whether they had been removed.

From the experiments which have been stated, it appeared to Sir Henry Englefield, that Miles's eye was not deprived of its power of adjustment; and, by whatever circumstances my own judgment might be

deceived, or rendered partial, there was nothing by which his could be biassed, as he could have no object in view, but the promotion of science. His knowledge of optics, and his habit of making experiments, are the best pledges of these having been as accurately performed as the nature of the subject admits of; for, certainly, the sources of fallacy, in optical experiments, are numerous. Those that have been related, to be made with perfect accuracy, should be tried upon the eye of a person skilled in optics, and accustomed to such experiments; and whose eye had been deprived of the crystalline lens, without having received the slightest degree of injury in any of its other parts.

The experiments were instituted in the Isle of Wight, which prevented me from requesting several of my friends to be present at them, whose knowledge of the subject would have made me desirous of their assistance.

Haller mentions the case of a nobleman, from whose eye the crystalline lens had been extracted, who used glasses, and could see with them objects at different distances. As this was an observation made upon a particular friend of his own, and as he refers to Pemberton, who mentions a case of depressed crystalline lens, in which no such effect took place, it is natural to suppose, that he had given considerable attention to the subject; and that, although the experiments he instituted are not mentioned, the opinion was not advanced, without what appeared to him sufficient authority.

Changes in Corneal Astigmatism

The following is an excerpt from "Changes in Corneal Astigmatism" by J.W. Paker, Optical Journal and Review, April 11, 1931, p. 21-22:

The rudest awakening in Optometric science I ever experienced was in watching a radical change in the amount of astigmatism through the ophthalmometer. Patient was a lady, in the thirties, who had been operated on twice for convergent strabismus. Both the internal recti had been cut and indications were that both muscles were either detached or else attached so far back as to be useless.

The left eye, which was the poorer of the two, showed a minimum of 3.00D. of Ast. against the rule, and this amount would actually double for a few seconds and then return to the minimum. This change was evidently due to some action of the oblique muscles and occurred when the eye was directed toward the tube, while there was a slight turning of the head.

The case is of no practical interest except in showing the possibility of corneal astigmatism being functional rather than structural. Another case was that of a lady, also in the thirties, who came to me wearing plus .75 spheres. These were fitted by the assistant to one of the foremost oculists in Kansas. The chief symptom complained of was excessive lachrymation. In this case the ophthalmometer showed .75D. Ast. plus, axis approximately 90, subjectively, plus spheres unacceptable. Also, please note, in the subjective testing, the axis varied markedly and .50D. plus cylinders were preferable to .75D.

After six or seven vigorous muscle treatments, the ophthalmometer showed a decrease in Ast. Subjectively, there was no hesitation in finding the axes 75 and 105. The cylinders were cut to .37 and, to my surprise, patient also accepted a 1.25D sphere for each eye. The excessive lachrymation which has been usually attributed to Ast. began to lessen immediately after the second muscle treatment. This seemed significant.

The first case mentioned above belongs to the freak class, and a similar one might not be met with again in years. The second case, however, is typical of several met with in the last few years, and should furnish food for serious thought. More and more, I am convinced that much suffering and many mistakes in refracting are due to failure to give the external muscular system proper attention.

[...apparent digression...]

Excuse the apparent digression, but the point I want to bring out is: That corneal astigmatism does change and often lessens and sometimes disappears after thorough

muscle treatments.

Likewise, the symptoms attributed to refractive errors often vanish after muscular treatments, even though the refractive error remains. In other words, the symptoms may be due to wrong muscular condition and not to the refraction. This will account for some of the "miraculous" cures made by the kind of doctors whose slogan is "throw away your spex."

The following reports and experiments show that the cornea has the capacity to dramatically change its shape over short periods of time. I have included some work on bird corneas, for what it's worth. For the birds studied, corneal change is a regular part of accommodation (focusing). Certainly, in the human eye, the change the cornea during accommodation, if it exists, is very slight. However, the effects may indeed be very significant over time. A better understanding of how the muscles of the human eye affect the cornea could bring us far towards finding cures and determining preventive measures for myopia and astigmatism.

ACCOMMODATION IN THE LENSLESS EYE-TO WHAT IS IT DUE?

A. EDWARD DAVIS, A.M., M.D.

Originally published in *Manhattan Eye and Ear Hospital Reports*, vol. 2 (Jan. 1895), pp. 41-56

My attention was first called to this very interesting physiological question by a remarkable case of this kind which occurred in my private practice. On looking over the literature of the subject, I find the question of "accommodation in the lensless eye" still an unsettled one. Leading authorities - Helmholtz, Donders, Mannhardt - on the one hand, asserting that the lensless eye is devoid of accommodation, Donders* declaring that his "*investigations had led him to the conviction, that in aphakia not the slightest degree of accommodative power remains.*" On the other hand, eminent authorities - Förster, Woinow, von Graefe, Loring - contend that accommodation does exist in aphakial eyes, Loring** affirming "that occasionally a considerable, if not a large degree of accommodation may exist, even in a lensless eye."

*Donders, *Accom. and Refrac. of the Eye*, 1864, p. 320.

**Flint, *Physiology of Man*, 1875, vol. v., pp. 110, 111.

Not only have these eminent authorities disagreed on the abstract point "of accommodation, or no accommodation in the lensless eye," but, unfortunately, those who have agreed on one side or the other, do not agree as to how, if present, it is brought about; or how, if not present, it still appears to be present. Undoubtedly the absence of the same or uniform tests accounts for a great deal of this difference of opinion. That some lensless eyes possess the power of adjusting themselves to seeing objects at different distances (call it accommodation, or what you will), with one and the same glass, and that glass held at one distance from the eye, there is no question in my mind whatever. *How* this adjustment or accommodation is brought about is quite a different question.

Besides my own case, I am able, through the courtesy of Dr. Webster, to report a similar case which occurred in his private practice.

CASE 1. Mr. E. C., aged 42, chef. On January 27, 1894, I removed a sclerosed or "black" cataract from his right eye, doing an iridectomy upward at the same time. His vision at time of operation was: R. E. 20/70, L. E. 20/40. Jaeger No. 12 at ten inches R. E., and Jaeger No. 9 at ten inches L. E. Though his vision was this good he could not recognize members of his family or friends on the street, had not worked for five years, and insisted on the operation being done. February 21st, about three and one half weeks after the operation, the ophthalmometer showed astigmatism with the rule 4.50 D, axis 90 + 180 -. April 20th, less than three months after the operation, the ophthalmometer showed absolutely no

astigmatism. V. R. E. 20/10 (Snellen) With + 11.50 D_s. He read Jaeger No. 1 at ten inches with + 15.50 D_s. These glasses were accordingly ordered, + 11.50 D_s for distance, and + 15.50 D. for reading. I saw nothing more of the patient till six months later, October, 1894. The reason for his visit to me at this time was, not because the eyes were not doing well but because he thought he might be "straining" them; as he informed me he had been using his distance glasses all the time, both for distance and reading, having discarded his reading glasses after a few weeks' use. I doubted the truth of his statement at first, never having seen such a case before. On testing his vision I found he could, with + 11.50 D., his distance glass, which I took the precaution to measure and verify, read 20/10 (Snellen); and with the same glass, held at the same distance on nose, he read Jaeger No. 1 from fourteen to eighteen inches. October 8, 1894, I presented the case in person before the New York Ophthalmological Society (before which he kindly consented to go). The members of the society were divided in their opinions as to how the patient was able to accommodate for the near point with his distance glasses on. February 4, 1895, I saw the patient again. He still read Snellen 20/10 -, and with same glass Jaeger No. 1 from eight to twenty-two and one half inches. This was such a remarkable increase in his relative range of accommodation for the near point, that I decided to make a thorough examination of his eye in every respect, accurate measurements of his cornea, and to ascertain, if possible, how such a result could be brought about. I accordingly subjected him to the following tests :

Subjective tests:- 1 (a) Acuteness of vision for distance and near, point, with the distance glasses; (b) same with tipper lid held up ; (c) same with a few drops of cocaine instilled and speculum to hold lids open; (d) adding weak plus or minus glasses to his distant glasses and noting changes in acuteness of vision; (e) to repeat the above tests with the opposing eye uncovered, and with the visual lines converging. 2. Tested his acuteness of vision for a distant point of light (after Donders' method), under the five conditions imposed it) test No. 1.

Objective tests. - 1 (a) Measurement, with the ophthalmometer, of the radius of curvature of the two chief meridians of the cornea at the point where the visual line intersects same; (b) the same measurement five degrees to the outer side of this point, which was close to the apex of the cornea in each of the cases here reported, as the angle alpha was positive and about five degrees in each. 2 (a) With the Placido disc* removed from the cylinder of the ophthalmometer, and with the patient looking five degrees to the inner or nasal side, to note if any changes were made in the relative position and size of the corneal images when the eye changed from looking in the distance to a near point,** *the eye not changing its direction*; (b) the same test with lids held open with a speculum ; (c) with the opposite eye uncovered both of the above tests were repeated. 3. Ophthalmoscopic measurements of the fundus Were made to see if any change in depth occurred when the eye changed from a state of rest to accommodative efforts. 4. The size and shape of the pupil, if clear, or partially filled with membrane, activity, etc., were noted.

* Meyrowitz replaced this with a smaller disc placed back of the arc with the correct numbering and an indicator, so that the axis could be ascertained.

** The distant object at which the patient looked at in this test was the window of a house reflected from a French-plate mirror, which I had fixed on a revolving stand just back of me and facing the patient and window at which the ophthalmometer was placed. The houses reflected by the mirror were about one hundred feet distant, the eye observed being

perfectly relaxed, therefore, when looking at them. The near point was a fine, black dot, 2 mm. in diameter, near the end of a narrow strip of white paper, which I pasted on the end of the tube, turning the strip of paper at a right angle to the tube and letting the end extend far enough to be five degrees from the centre of the tube. I pasted two of these slips on the tube, one to the side, one above. The distance from the end of tube to the observed eye was eight inches.

All of the above tests were repeated with the eye under the influence of a mydriatic.

The results of these tests in my case were: 1. V. R. E. = 20/10 (Snellen), with + 11.50 D_s (1 / 3-1/2). With the same glass, and without moving it on his nose, he read Jaeger No. 1 from eight to twenty-two and one-half inches, holding the type in the usual reading position, that is, slightly below the centre of the glass. he did not tilt his head or the glasses. When the type was held up higher, directly in front of glass, he could not read quite so well as when he held the print a little lower, as the print is held when reading naturally. I repeated this test time and again, and had Dr. M. L. Foster present on two occasions. Holding the lid up with the finger or with speculum made no change in his acuteness of vision whatever, either for distance or near. With the eye scopolamized (1/10 per cent. solution instilled every five minutes for thirty-five minutes, then a wait of one half hour), the distant vision was still 20/10 -, while the relative range for the near point, Jaeger No. 1, was nine to twenty-one inches; his relative range of accommodation for the near point was reduced but two and one half inches. When the left eye was covered in these tests, it was seen to turn in and the pupil to contract for the near point. Leaving the left eye uncovered made no change in any of the tests. A +.50 D. spherical glass added to his distant glass made him see worse for the distance ; with a -.50 D. spherical added he saw the same, while a -.75 D. spherical made him see worse. From this, it would seem that he had accommodative power to the extent .50 D., even for the distance. 2. Having the patient look at a point of light (a portion of lamp flame seen through a round hole, 3 mm. in diameter, in a piece of cardboard) twenty feet distant with his distance glasses on and adding a + 1/263 ((1/26 () - 1/32) made no change in the circle of light, neither did a + 1/160 (.25 D.). A +1/80(.50 D.) elongated the circle of light in the vertical meridian. It took a -1/80 to elongate the circle of light in the horizontal meridian. An effort of accommodation elongated the circle of light in the vertical meridian, just as the +1/80 spherical had done. When the lid was held up with finger, or with speculum, and when the eye was scopolamized, the test with the distant point of light was wholly unsatisfactory and contradictory. With the left eye uncovered and the right converging in the line of light, the tests were about the same as when the left eye was covered.

Objective tests. - 1. The ophthalmometer showed him to have absolutely no astigmatism. The radius of curvature at the point where the visual line intersected the cornea was 8.9 mm.; at the apex 9 mm. When the patient looked five degrees to the inner side of the tube (relative to the eye, the nasal side), just by the end of slip of paper I had pasted on the tube, into the distance; I approximated the images of the mires in the horizontal meridian so that they just touched. Then, without changing the direction of his eye, I had him focus on the black dot on the end of strip of paper. With his greatest effort at accommodation the images overlapped to the extent of one half diopter perhaps. The cornea moved forward a little, too, as was shown by the images getting out of focus, and the instrument had to be pulled slightly away from the eye in order to get them in perfect focus again. Or, if I had him focus on the black dot first and

approximated the images, then let him look in the distance, the images separated slightly and the instrument had to be pushed toward the eye to get it in perfect focus again. Letting the patient look still in the same direction, but turning the arc of the instrument in the vertical meridian, and repeating the above experiments, the results were just reversed; that is, if I approximated the images while he was looking in the distance, then had him focus on the near point, the images separated slightly; but, if the images were approximated while he focused on the near point, and then looked in the distance, they overlapped about one half diopter. The same changes took place when the lids were held open with a speculum, and even when the ciliary muscle was paralyzed with scopolamine. The changes produced in his cornea must, therefore, have been produced by the action of the external muscles of the eye.

2. It was impossible to detect any change in the depth of the fundus of the eye with the ophthalmoscope when the eye changed from a state of rest from looking in the distance with opposite eye to a state of accommodation. The fundus of the eye was normal, with the media perfectly clear. 3. The shape of the pupil is an irregular oval, from the iridectomy, and free from membrane, except a very narrow margin at the edge, though, when I reported him to the New York Ophthalmological Society, and before I had made a critical examination, I had thought there was more membrane present. The transverse diameter of his pupil is 3-1/2 mm., the vertical about 7 mm. (see Fig. 1, A). B., Fig. 1, shows pupil dilated and some remains of membrane at periphery.

FIG. 1.

Case 2. Master W. O. B.,* aged 13. School boy. Dr. Webster saw this patient first in Nov., 1891, when ten years of age, brought to him for double congenital cataract. The patient had already had eight discissions done on the left eye, the first one in Nov., 1890. When Dr. Webster saw him his vision was: R. V. = 20/70, no improvement with glasses. L. V. = 20/100, with + 10 D. November 28, 1891, Dr. Webster did a discission of the membrane in the left eye. January 19, 1892, L. V. = 20/70 with 13 D.

* This case, a private patient of Dr. Webster's, has been reported by him in a series of cases as: *A Case of Congenital Cataract, both Lenses Removed by Operation, Arch. Pediatrics*, New York, Nov., 1893, p. 432.

"As the patient saw with the right eye about as well without a glass as he saw with the left with one, I concluded that he might as well go about without glasses for distant vision, and I gave him for reading, Right, plain glass. Left, +16 D.

"March 14, 1893. - The patient returned for further advice, and I found he was wearing the glasses all the time, which I had prescribed for reading only. On testing him I was surprised to find that with his left eye, with his glass, +16 D. he had Vision 20/20, while with the same glass he read Jaeger No. 1, at fourteen

inches easily. This looked as though his aphakial eye still retained its power of accommodation."

Subsequently the right lens was removed by discission and *linear incision*, but no accommodation was observed, though his vision with a +13 D. was 20/50. I saw this patient first, March 16, 1895, and subjected him to the same tests as in my own case, with the following results: 1. V. R. E. - 20/300, with +13 D. V. L. E. 20/20 -, with +16 D. Jaeger No. 8, at ten inches, right; Jaeger No. 1, from ten to eighteen inches, left, with his distance glass, not moving it, and looking directly through its centre. His accommodation for the near point for the left eye had increased to ten inches from fourteen inches, since Dr. Webster saw him two years previously. His right eye, however, not only had no accommodative power for near point, but distant vision in it had decreased from 20/50 to 20/200, due to a membrane filling pupil. Holding the lid up with the finger, or with speculum, or even paralyzing the left eye with scopolamine did not change his vision for the distance or near point, he still seeing 20/20 - in distance, and Jaeger No. 1. ten to eighteen inches for the near point, but not quite so easily as before. With the right eye uncovered he could read more easily, but no better. Both + and - .50 D. spherical glasses added to his distant glass, made him see worse in the distance, especially the - .50 D. 2. Looking at a distant point of light and adding a +1/263 or -1/263 to his distance glass had no effect, neither was he positive of a change in the circle of light with a + or a - 1/160 (.25 D.). A + 1/80 (.50 D.) elongated the circle of light into a vertical oval. A - 1/80 (.50 D.) elongated the circle of light into a horizontal oval. An effort at accommodation elongated the circle of light slightly in the vertical meridian. Holding the upper lid up had but little effect in this test, but when the eye was under the mydriatic action of scopolamine, the tests for point of light were unsatisfactory.

Objective tests. - 1. The ophthalmometer showed left eye to have astigmatism with the rule, 3 D. axis 65 + 155 -. The radius of curvature of the meridian at 155 was 8.5 mm., at 65 it was 7.9 mm. At the apex of the cornea the radius of curvature of the meridian at 155 was 8.5 mm., at 65 it was 7.85 mm. When this patient looked in the distance then focussed for the black dot on the end of paper, under the same conditions as in Case No. 1, there was absolutely no change in the relative positions or size of the corneal images. Furthermore, the images of the mires remained in perfect focus, showing that the cornea had not moved forward or backward. Leaving the right eye covered or uncovered made no difference in the tests. 2. The ophthalmoscopic examination was the same as in Case No. 1 - negative, except to show that the fundus of the eye was normal and media clear. 3. Pupil circular (perhaps slightly oblong in the vertical meridian), active, 3-1/2 mm. in diameter, but considerably incroached upon at the inner side by a crescentic band of membrane, giving it somewhat the character of a stenopæic slit. This slit was 2 mm. wide and 3-1/2 mm. long, and was crossed by two very fine threads of membrane, horizontally (see Fig. 2, A). When the pupil was widely dilated it was filled up entirely by a dense membrane, except the small central opening already described (see Fig. 2, A'.)

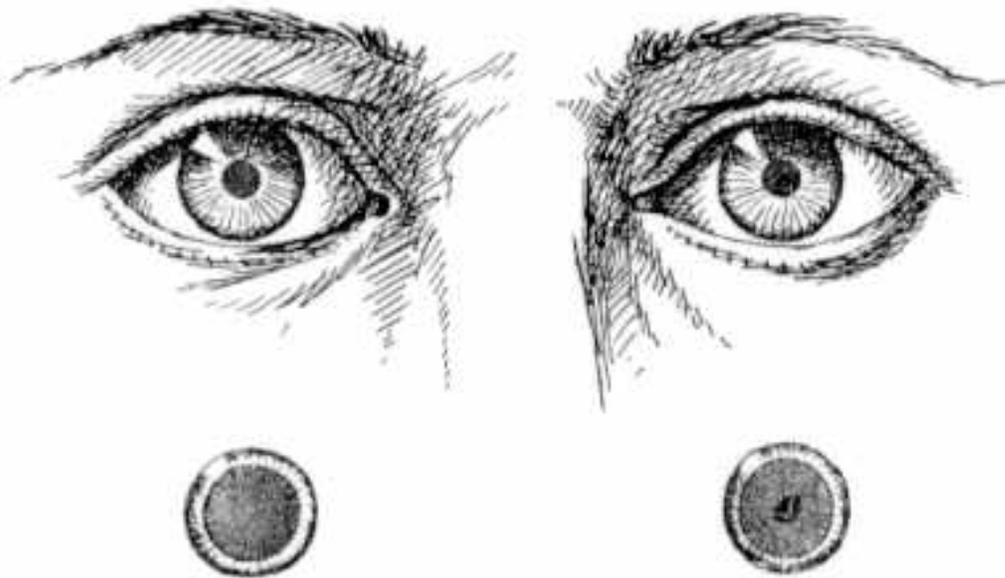

FIG. 2.

Such is the report of the two cases. The question, "*How* was the accommodation brought about in these cases?" presents itself for consideration. Before giving my own views, I wish, first, briefly, to present the views of some former writers on the subject. Ramsden and Horne* were among the first to examine aphakic eyes for accommodation. They were of the opinion that the accommodative power present in such cases was due to the cornea becoming more curved and moving forward at the same time. Thomas Young ** did not believe there was any accommodation left in the lensless eye, but was only tolerably well satisfied with his tests in proving its absence. Von Graefe *** was of the opinion that the aphakic eye retained some accommodative power. Helmholtz and Donders were quite positive that the lensless eye retained no accommodative power, and Donders **** declared himself very forcibly in his text-book on this subject, claiming that not trace of accommodative power remained in such cases. And later, in Graefe's Arch. of Ophthal., xix., p. 63, he still holds to this view. I do not consider Donders' tests, however, as conclusive, as the two which he based his conclusions on mainly were both subjective. To wit: 1. That an aphakic eye when accurately fitted for a distant point of light will see it as a circle, and where the patient makes the greatest accommodative efforts the shape of the light is not changed, but is only made smaller concentrically, due to a contraction of the iris; on the other hand, when a weak plus or minus glass (1/300) is placed before the eye, with its proper correction on, the circle of light is converted into a vertical or a horizontal oval. 2. That the acuteness of vision, with the distant-glass on, should be the same in a certain or stated interval, *e.g.*, 1/2 for distance and 1/2 for some near point. By these two requirements of Donders, then, both of my cases had accommodative power left; for, as regards the first requirement, both, by accommodative effort, could convert the distant circle of light into a vertical oval. Furthermore, in each case it took as strong a glass as +1/80 to produce a like effect, and -1/80 to convert the circle into a horizontal oval (see test No. 2 above in each case). As to his second requirement: Case I. read with the same glass, + 11.50 D., Snellen X. at twenty feet, V. at ten feet, and Jaeger No. 1 at eight inches. Case II. read with the same glass, + 16. D., Snellen XX. at twenty feet, X. at ten feet, and Jaeger No. 1 at ten inches. Another case, reported by Dr. Silex, which will be referred to again, complied with both of Donders' requirements, so that it may be taken as proven that Donders' tests were wholly inadequate to decide the question at issue.

** Cited in *Graefe-Samisch Augenheilk., Path.Therap.*, vol. v., p. 444

*** *Loc. cit.*, p. 444. Also original article, *Graefe's Arch. f. Ophthal.*, Bd. II., Abth. i., p. 188. **** *Donders' Accom. and Refrac. of the Eye*, p. 320.

In 1872 Professor Förster,* of Breslau, reported a series of twenty-two cases of apparent accommodation in aphakial eyes. They ranged in age from 11 to 74 years, the younger patients having more accommodative power than the older ones. His experiments were not decisive, however, as he did not leave the distance glasses on when he tested for the near point. Förster was of the opinion that the accommodative power present in these cases was due to the cornea becoming more curved. This was more or less of an assumption on his part, as he did not make the proper objective tests to prove his statement. However, that the curve of the cornea can be changed, by accommodative effort, to a slight extent at least, in the lensless eye, is shown by my case. In the normal eye the change in curvature of the cornea, by accommodative effort, is some cases very marked. The most marked case of this kind that I have seen occurred in the person of Dr. C. H. Johnson, a former House-surgeon at the Manhattan Eye and Ear Hospital. The ophthalmometer showed him to have ordinarily an astigmatism .50 D. ax. 90+ 180-, both eyes. He could, however, without in any way changing the direction of his eye, voluntarily, by efforts at accommodation, change this in the right eye to 2 D., and in the left to 1.50 D. he was able to do this while the upper lid was held up with the finger, showing that it was not due to lid-pressure. He did this many times, and the same change was observed by a number of the staff at the hospital. Desiring to know if this change was due to the action of the ciliary muscle or to that of the external muscles of the eye, I wrote to Dr. J. M. Ray of Louisville, where Dr. Johnson now resides, to put Dr. Johnson's eyes under the influence of a mydriatic (the doctor permitting), and in that way eliminate the question of the ciliary muscle. I give his report:

**Klin. Monatsbl. f. Augenheilk.*, Erlangen, 1872, B.X., p. 39 *et seq.*

V.R.E. = 20/20; V.L.E. = 20/20. Ophthalmometer shows astigmatism with the rule .50 D. ax. 70 + 160 - Rt. ; 90 + 180 - Lt. "When he made an effort at accommodation without changing the direction of his eye, the astigmatism can be seen to go up to 2 D. in Rt., and 1.50 D. in Lt. Scopolamine, four instillations of 1/2 per cent. solution, apparently paralyzed accommodation. Then with the ophthalmometer the astigmatism still seems to increase in the right eye to 1.50 D., and in the left to 1. D."

From this it appears that, in Dr. Johnson's case at least, the change in the curve of the cornea is brought about mainly by the external muscles of the eye, as the influence of the lids and ciliary muscle was eliminated. Again, in my case, the external muscles must have caused the slight change which took place in the cornea, as when his eye was under the influence of a mydriatic the change could still be observed.

Woinow* reported a series of eleven cases of accommodation in the lensless eye in 1873. The patients ranged in age from 12 to 60 years. The fault in the tests of Woinow's cases consisted in the fact that he took the relative range of accommodation for the near point only. This relative range was comparatively small, amounting in no case to more than six inches (see *loc. cit.*, p. 116), and averaged on the whole about 1/20. He failed also to make adequate objective tests, and in closing his paper acknowledges he can

give no positive answer as to the cause of accommodation in aphakial eyes, but believes it was due to three factors: 1. To the anterior surface of the vitreous becoming convex after the lens is removed, and in that way acting as a plus lens, 2. To the action of the ciliary muscle and a change in the depth of fundus from that action. 3. Action on the globe of the eye of the external muscles. He thought, also, that a change in the curvature of cornea [might be a factor, but finally eliminated that.

**Arch. f. Ophthalm.*, Berlin, 1873, Bd. xix, p. 107 *et seq.*

As to his first factor, that the anterior surface of the vitreous became more convex after the lens was removed (which he discovered in two cases by a weak image reflected from it in the upright position), and in that way acted as a plus lens to converge rays of light, I think he is mistaken. This simply from the fact that the index of refraction of the cornea, aqueous and vitreous, is the same for each, and, consequently, as pointed out by Donders,* "we have in the aphakial eye only one refracting surface to take into account, namely, the anterior surface of the cornea," As to his second factor, I believe the ciliary muscle has but little effect on the depth of the eye. I am brought to this conclusion because, when the ciliary muscle was paralyzed in the two cases that are reported by me, the accommodation remained exactly the same in one as before the mydriate was used, and was reduced but about two inches in the other. Furthermore, he states in his own paper that a quota of accommodation remains in such eyes after they have been atropinized, *e.g.*, where it was 1/28 before using atropine, after using it the accommodation was 1/40. As to the third factor, I believe the action of the external muscles do have some slight effect in changing the length of the eye in aphakia, but very little, if we can judge from my first case. In the normal eye they may have more effect, as shown in Dr. Johnson's case.

*Donders, *Accom. and Refrac. of the Eye*, p. 310.

Loring reported a remarkable case of accommodation in the lensless eye to the New York Ophthalmological Society, April, 1879, and the same case to the American Ophthalmological Society in 1870. He later reported the same case at length for Flint's *Physiology of Man*, p: 110 *et seq.* Roosa quotes the case in full in his text-book, *A Clinical Manual of Diseases of the Eye*, p. 57.

Loring's case occurred in the person of a young woman, 18 years of age, who had had both lenses removed by discission five years previous to his seeing her. "The pupils were round, free from membrane and active. With + 1 / 3 1/2, the patient read with either eye fluently Snellen XXX. and was able, with both eyes, to pick out most of the letters of XX. at twenty feet. She could read No. X. at ten feet, and No. V. at five feet. With the same glass, and with no change of position on the nose, she read No. 1 1/2 Snellen fluently, holding the book naturally at twelve inches, which was about the distance at which she usually read. The book was then gradually withdrawn, the patient reading aloud while this was done. It was found that twenty-one and a half inches was the greatest distance at which No. 1 1/2 Snellen could be read. She read No. 1 Jaeger at twenty inches. The book was then advanced inch by inch, the patient reading aloud, till the book was within five inches of the eye. Inside of this reading was impossible. These experinients were tried over and over again by myself, and were finally repeated in the presence of a brother oculist. This would give the patient an adaptability of the eye for different distances from twenty feet (or parallel rays) to five inches; or, in other words, an accommodation of 1/5 (A=1/5), and a relative

accommodation for the very finest print from twenty inches to five ($A = 1 / 6 - 1/2$)."

Loring also cites the papers of Förster, and Woinow, already quoted in this paper; also a paper by Arlt* in which is reported the case of a young man who had after cataract extraction a marked amount of accommodation left. "With convex $1 / 3 - 1/2$, could read both at six and at twenty-four inches, and could recognize the hands of a steeple-clock, at a distance of more than five hundred paces, with the same glasses: but, as neither the size of the print nor that of the clock is given, no accurate calculations can be drawn from the case." Commenting on his own case Loring says: "The case observed by me would then appear to be the first - as it is certainly the most remarkable - subjected to the recognized standard test of vision."

Die Krankheiten des Auges, Prag., 1858, bd. ii., S. 348.

Unfortunately even with the report of so remarkable a case, Loring, like all before him, failed to make adequate objective tests, and so left the question of accommodation in the lensless eye unsettled. His patient promised to return to have these further tests made, but failed to do so. Loring's remark (through no fault of his own, however,) on Woinow's and Förster's failure to make the proper objective tests applies with equal force to himself, e.g., "It is to be regretted, and it certainly appears a little strange, that in neither Förster's nor Woinow's cases, was either the optometer or ophthalmoscope used in the elucidation of this problem." Withal, however, he was of the opinion, "that occasionally a considerable, if not a large degree of accommodation may exist, even in the lensless eye."

Dr. Paul Silex's* paper "On the Question of Accommodation in the Aphakial Eye," in 1889, is the latest contribution on this subject with which I am acquainted. Some cases observed in the Berlin eye clinic induced him to make a careful examination into the subject.

*Knapp's *Arch. Ophthalm.*, vol xviii., p. 274: translated by H. Knapp.

The most marked case occurred in a boy, aged 14, who had had a cataract removed five years previously by repeated dissections. This patient complied with both of Donder's requirements, that is, his acuteness of vision was the same in a given interval, e.g., distant vision was $6/12 = 1/2$, and his near vision was $25/50 = 1/2$. And as to the slight point test Silex observes that it was just the reverse in this case. When he had glasses of slight value added to his distance glass the patient gave contradictory answers, but efforts at accommodation on the intersection of two fine threads near at hand, and in the line of vision of the observed eye for the distant point of light, changed the light into a vertical oval. Silex did not depend on these two requirements, but made objective tests with the ophthalmometer. I must confess, however, that I do not understand his method of testing with that instrument. He says: "The patient left his glasses on, as without them his fixation would have been unsteady. He had to look alternately at the tube of the instrument and at small printed pieces of paper held at reading distance from his eye a little down and in. In spite of the eighteen reflected images of the lamps, it was easy to distinguish those belonging to the cornea. The pupil contracted on convergence, the boy alleged to recognize the letters clearly, but the relative position of the images did not change."

First, I do not understand how the cornea was measured when the patient "kept his spectacles on." I have never seen it done, but perhaps I am unfortunate in that respect. It seems to me, too, that eighteen reflected images would be a little confusing, and make it anything but easy to distinguish those belonging to the cornea. Second, he says, "the relative position of the images did not change," and this, though the patient first looked at the tube then a little down and in at printed pieces of paper. This is wholly contrary to my experience with the use of the instrument. My experience has been that the least change in the direction of the eye changes the relative position of the corneal images. In fact, one of the chief precautions laid down as a guide in the use of the instrument, is that the observed eye shall look *steadily* at the centre of the tube; the least change from this, as a rule, causes a change in the relative position of the corneal images. By a change of direction of the eye of five degrees from the centre of the tube, I have a change of as much as one diopter in the amount of astigmatism; and for ten degrees, as much as two diopters. How far the doctor means by "a little down and in," I do not know, but, if as much as ten degrees, he certainly measured different points on the cornea, and his test would not hold. His conclusions from the tests were, "that the aphakial eye was devoid of accommodation," and the ability to read at near point in these cases was due in the main, "to the unusual faculty of certain ametropes to overcome dispersion circles."

My own conclusion, from studying the history of the subject, and from the careful and complete tests made in the two cases here reported, is, *That the accommodation present in the lensless eye is due chiefly if not solely to the ability of the patient in such cases, to interpret dispersion circles.* The slight change in curvature of the cornea, and its slight advancement observed in some cases, may, in those cases account for some of the accommodative power present, but it is such a small factor that it may be eliminated entirely, especially since in some of the most marked cases of accommodation in aphakial eyes no such changes have been observed. How the change in the curvature of the cornea and its advancement are brought about, have been discussed in this paper already.

Although, as Loring says, "It would seem impossible that the ability to read the finest print at five inches (which was done in his case), even taking into consideration the magnifying power of the glass, could be due to the overcoming of the circles of dispersion," yet I believe such to be the case, and for the following reasons: First, to the great increase in size of the retinal images by the removal of the crystalline lens and replacing it with a lens in front of the eye. By this procedure the united nodal point is removed forward, and this, with the magnifying power of the glass in front of the eye, greatly increases in size the retinal images. Donders* has shown by calculation, that a convex lens of three inch focus, placed one half inch (usual distance) in front of the eye increases the retinal images in size one and one third times. By this one factor alone, then, the images of Jaeger No. 1. would be increased in size until they equalled (for the unoperated eye) Jaeger No. 2 or a little larger. Second, to the narrowing of the pupil. Where no iridectomy is done, this is due to the contraction of the iris as the result of convergence and an effort at accommodation; where an iridectomy is done to a partial filling up of the pupil by membrane, except a central opening. It is a well known fact that if the pupil is narrowed from any cause such narrowing acts as a diaphragm to cut off the peripheral rays of light entering the eye, and serves in this way to lessen the dispersion circles. Third, to the extraordinary acuteness of vision sometimes present after cataract extractions, *e.g.*, as happened in my case, where it was 20/10, double the ordinary acuteness of vision. I believe this fact contributed largely to the power of interpretation present in this case; for he had an

iridectomy and a clear pupil. Fourth, in some cases, to the patient not looking directly through the centre of the glass, but slightly outside of the centre, either by tilting the glasses, tilting his head, or not holding the reading matter directly in front of him. In my opinion, this fourth factor - in effect, a slight tilting of the strong plus glasses - assists the individual in interpreting dispersion circles chiefly by neutralizing the monochromatic aberration present in such cases. This is a point which no writer has hitherto called attention to in discussing this subject. Wm. Harkness* has shown that, "with a pupil four millimetres in diameter, the normal cornea produces monochromatic aberration to the extent of 1/33: and as there is no confusion of images in the normal eye, it seems probable that the crystalline lens exerts some compensating action. This suspicion is strengthened by the well-known fact that in aphakia, the acuteness of vision is nearly always improved by giving a certain inclination to the powerful convex glasses which are then necessary." Furthermore, this very fact of monochromatic aberration in the lensless eye, to my mind renders Donders' Light-point test more or less unreliable.

In conclusion, I might say that I believe this question of accommodation in the lensless eye would have been settled long ago had the proper objective tests been made. From one cause or another, not a single observer made all the tests necessary to settle the question, except for himself, and some did not succeed even in doing that. In fact, all of them together failed to make the requisite number of tests. Dr. Silex came nearer to it than any who had gone before, but he failed in one most essential feature, and that was to atropinize his subjects. Besides his one objective test was open to serious objections in its *technique*. Most of the observers were content to rest the case on mere assumptions and subjective tests. Even that most careful of observers, Donders, fell into this error; so that, the quotation he once applied to Wharton Jones and Wilde, in regard to their assertion, "that the radius of curvature of the cornea was shorter in the vertical meridian than in the horizontal," before they had proved it (even questioning if they should receive credit for their observation), can be equally as well applied to himself, and others along with him who had the same opinion in regard to accommodation in the lensless eye. The quotation was, "We see that in science also the quotation is sometimes applicable, that '*audaces fortuna juvat*.'"

They were right, I believe in their assumption, but failing to bring *sufficient* evidence to prove it, still left the question of accommodation in the lensless eye and its cause *sub judice*.

This Paper was delivered to the 1996 Annual Engineering in Medicine & Biology Society Symposium.

ABSTRACT

Over the past fifteen years we have evaluated numerous models of accommodation. Our task is to clarify these models by designing an automatically focused camera, with major emphasis of the capability of the retina to sense blur and feed this information back to the eye's lens for accurate focal adjustment.

Depth-of-field, or dead-band, poses a significant obstacle for the designer of an automatically focused camera. Our approach is to use noise to provide a scanning, or dither motion so that the lens will spend 80 percent of its time in sharp focus. Retina detection of blur can be simulated by a Charge Coupled Device (CCD), designed to produce a null when sharpest focus is achieved. The nature of blank-field accommodation is judged, and a prediction made about its long-term behavior.

INTRODUCTION

This paper's objective is to clarify the predictions that are implied in earlier block diagrams of the accommodation system. The diagrams do not provide active outputs which can be compared directly with the experimental data. The actual building of a working model from a block-diagram concept is challenging and will define, after review, the behavior of the normal system.

Thus, for instance, the noise that is seen in the system is not a defect, but rather is an essential design

requirement of a system that has dead-band. A scanning signal must be present if the system is to maintain accurate focal control. Other capabilities of this system, such as blank-field accommodation are part of the design, and are included in this model. The available measurements confirm most of the analog computer's predictions for the eye's dynamic focal control.

THE EYE AS A FOCAL CONTROL SYSTEM

Light rays from objects travel through the cornea, lens and ultimately arrive at the retina. At the retina they form a blur-circle which varies in size. The lens control system must act to drive the lens-plant towards the null (or in-focus) condition.

THE ORIGIN OF DEAD-BAND, OR DEPTH-OF-FOCUS

Optically, all eyes have dead-band. Dead-band varies, and is inversely proportional to the size of the aperture. The eye's dead-band in day-light is approximately ± 0.6 diopters, and at night, ± 0.3 diopters. Dead-band occurs because the lens of the eye can be varied in power without any detectable change in the sharpness of the image at the surface of the retina. [1]

A source point of light will produce a blur-circle on the retina. When this circle is larger than the retina cones, several cones "fire" producing multiple outputs. As the blur circle is focused to a point of light, only one cone will fire, producing a null. This null will exist throughout the dead-band. Because of this physical characteristic of the eye, a design-around of the control-system must be accomplished to deal with it, if the system is to maintain continuous sharp focus on the retina. Dead-band is schematically shown in Figure 1 and 2.

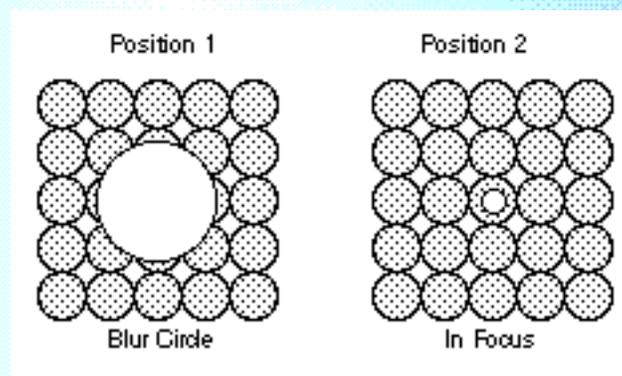

Figure 1: Shows how an expanding "disk of light" or blur circle falls on a wider area of neurons when the lens is moved towards and away from the retina. When the disk is smaller than the diameter of a neuron, only one neuron is triggered. This depth-of-field is approximately ± 0.6 diopters.

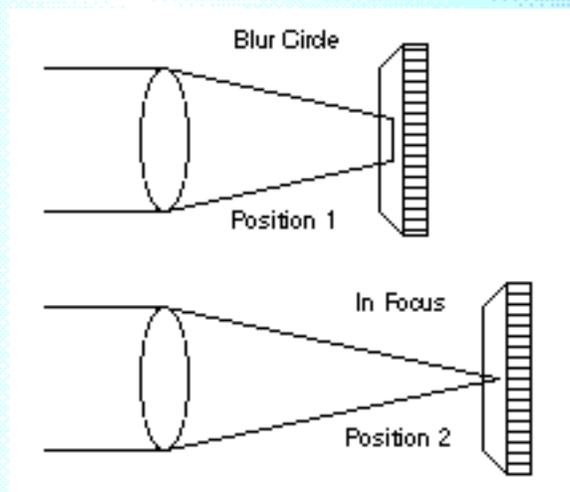

Figure 2: Demonstrates how lens motion relative to the retina creates variously a "disk-of-light", or blur circle. For a certain range of motion, no blur is produced on the surface of the retina.

A FOCUS NETWORK

The basic concept of a null-seeking network and system is that a cone/neuron will turn-on when struck by a photon of light. The output of the network depends only on the presence of light or no-light, and not on its intensity. A Charge Coupled Device (CCD) could be developed as an analog of this retina characteristic. [2] (A comparator amplifier, following the cone can be used to accomplish this conversion of an analog signal to a on-off level.) Figure 3.

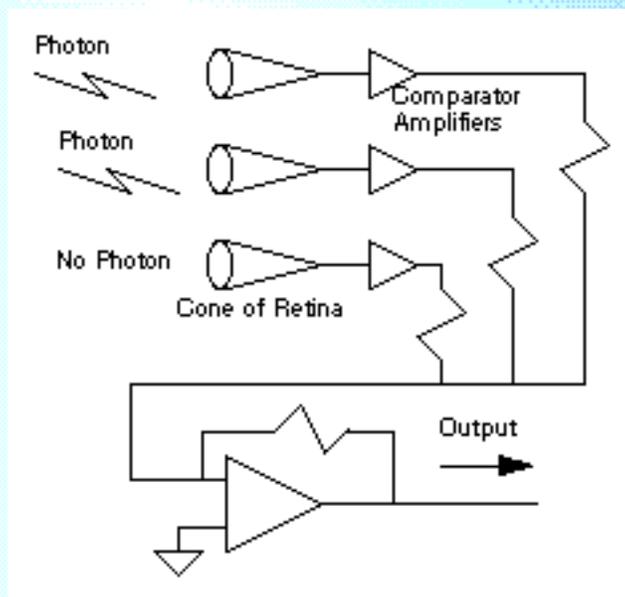

Figure 3: Demonstrates how an "artificial retina" can be designed to sense blur. While the retina probably uses a more sophisticated method of determining blur, an auto-focus camera could be designed and would work using this basic blur detection strategy.

THE SUMMATION OF NEURONS

When the signal blooms from being out-of-focus (positive or negative), more cones will detect photons, and the summations of neuron firing increases. This action produces an increase in output voltage, as the image goes out-of-focus. Figure 4. Lens control can occur only after the blur-circle strikes additional cones.

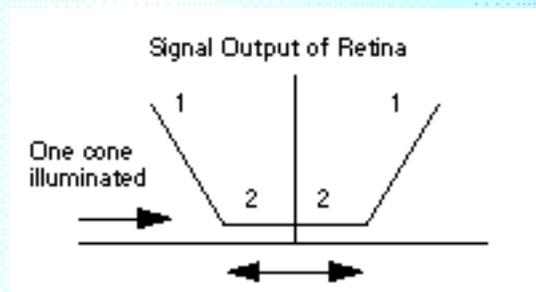

Figure 4: This figure demonstrates the nature of the signal produced by the artificial retina. Through the area of dead-band, the signal is constant. When the blur-circle begins to exceed the edge of the dead-band, a rising signal is produced.

THE OUTPUT OF THE OPERATIONAL AMPLIFIER

The retina senses the increasing voltage which is used by the control system (in combination with a dither signal) to produce a null-seeking action. The dither, or noise will -- on the average -- center the lens in the middle of the dead-band. This system will produce sharp focus for perhaps 80 percent of this time when the eye is viewing an object. Obviously, we are not objectively aware of the short excursions that occur when the lens exceeds the edge of the dead-band as the system scans the range of sharpest focus. Figure 5.

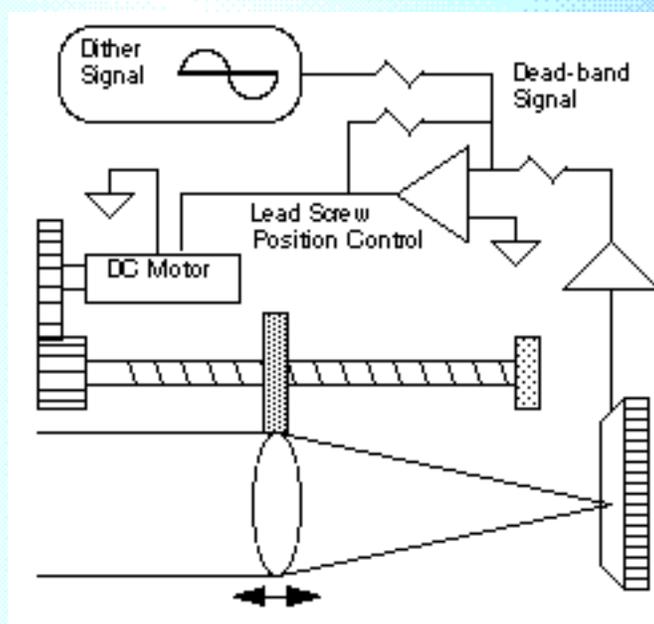

Figure 5: This diagram shows how the accommodation system behaves in actual operation. Since blur cannot be detected when the lens is inside the dead-band the focal state of the lens will "drift" until it exceed the edge of the dead-band. The system must use negative feedback to "kick" the lens towards and

into the dead-band. This type of motion is seen with an infrared optometer.

CONSTANT DITHER IN THE LENS SIGNAL

To center the lens, continual lens motion must be induced in the system. This can be accomplished by a sine-sweep, dither, or some other noise-type of signal. In the case of the eye, random motion (noise - from 0.25 to 4 hertz) is seen in lens motion -- as measured by an infrared optometer. [3,4] The need for this type of signal should be obvious to most control-system designers, where static friction or dead-band exist in the control system.

IMPLEMENTATION OF A RETINA-LENS AUTOMATIC CONTROL SYSTEM

The full implementation of the control system requires some mechanical changes in the "plant" to simulate the eye's behavior. The manner in which the muscles support the eye's lens has been discussed in many other texts and dissertations. [5]

Because of a need for high focal accuracy we cannot build a sphincter-muscle-lens system. We can, however, build a "plant" that will accomplish the same result. For this model, we show a lead-screw that is driven by a Direct Current (DC) motor. Thus by high-gain amplification of the output of the retina, and by lead-screw adjustment of the lens, we can insure that the lens is always servoed to the output of the retina for continuous focal adjustment. Figure 6.

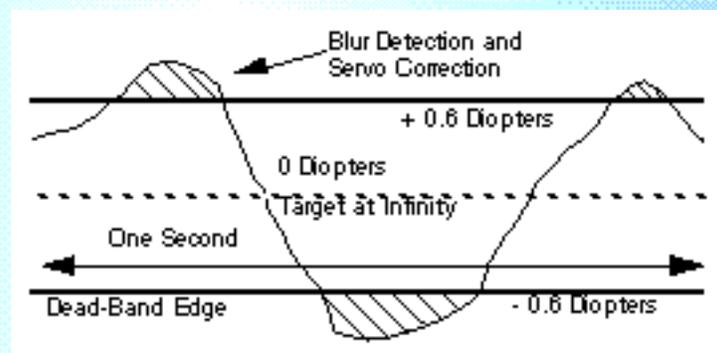

Figure 6: This model of an auto-focus camera shows how the signal derived from the surface of the retina is used to control the positioning of the lens relative to the retina. While more difficult to design, the lens power could be changed by using the lead-screw to change the power of the lens -- rather than the position of the lens. The control-system would behave in the same manner in either case.

The lead-screw will constantly change the focal position of the lens and the sharpness of focus on the retina. This type of signal is seen in the human eye, and is a normal condition. The continual motion of the lens will cause the retina to provide a changing signal. Proper use of this signal insures that the lens is within the dead- band most of the time. The net result of this control-action is a signal almost identical to

the neurological signal seen when the output of an infrared optometer is recorded on a strip-chart recorder. [4] A graphic sketch is shown in Figure 5.

A BLOCK DIAGRAM OF THE SYSTEM

The complete block diagram of the retina-lens system that captures the basic accommodation characteristic has been previously published. See Figure 7 [6] The action of the model is such that when the eye is looking at infinity (zero diopters) visual environment, the lens will oscillate between ± 0.6 diopters, as long as the individual looks at infinity.

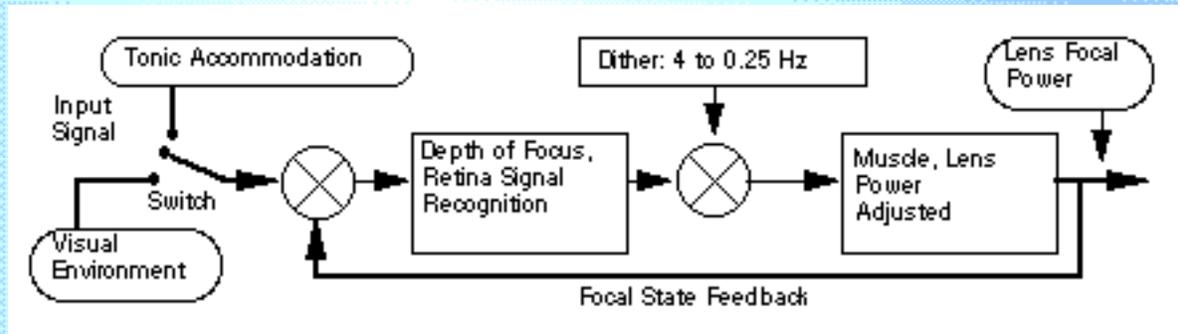

Figure 7: This diagram shows the basic building signal processing blocks of the accommodation system. The model produces an output (lens power) that is almost identical to the measurements made with an infrared optometer.

When the object is moved closer, say to -3.0 diopters, the lens of the eye will change by $+3.0$ and then oscillate by ± 0.6 diopters. Thus we have designed a visual control system that continuously monitors and tracks its visual environment. This model is consistent with other proposed dynamic models for the eye.

ANALOG COMPUTER IMPLEMENTATION OF THE BLOCK DIAGRAM

Our next step is to convert the block diagram into an analog computer and to compare the output with the response as seen by an infrared optometer. A major feature of the model is the requirement that the system must have a stand-by, or reference position when blur cannot be detected. A control system will typically drift into the stops, unless a reference signal is supplied. This simulation is accomplished by a switch which selects a -1.0 volt level when the eye is in "conscious darkness", or if blur cannot be detected. A typical value for the dark focus of the normal eye is -1.0 Diopters. [3] Figure 8.

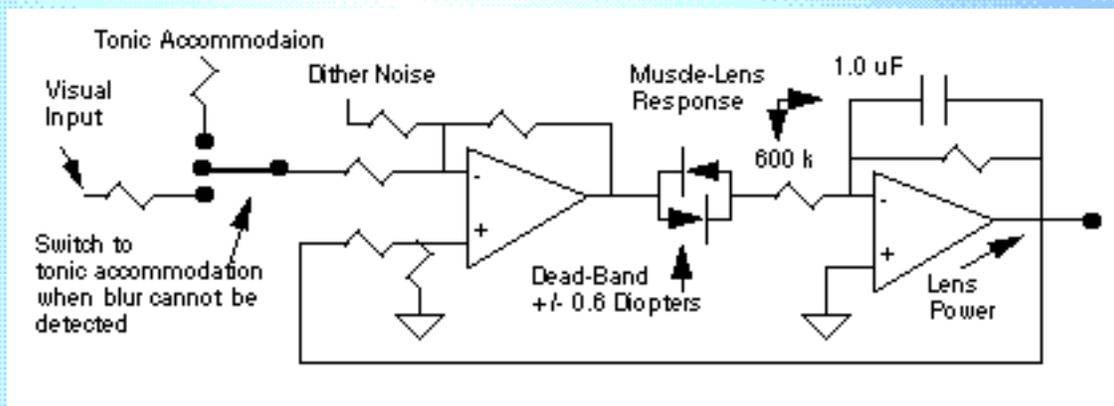

Figure 8: This diagram shows the implementation of the various accommodation blocks into a design that will work to effectively control the lens power of the eye.

FUTURE ENHANCEMENTS

The above presentation is a simplified version of accommodation. In future model enhancements, we will incorporate a tonic accommodation amplifier which will show that tonic accommodation will track the average value of accommodation. This response has been suggested in a previous study. [3] We can also expect that the tonic accommodation system will show a time-constant response of approximately 100 days. [7]

CONCLUSIONS

Previous models of accommodation have restricted their attention to the muscles that surround the lens of the eye. This model concentrates on the image processing and feedback control that must occur at the surface of the retina.

ACKNOWLEDGMENT

We acknowledge the long-term assistance of Dr. Karel Montor, The United States Naval Academy, and Dr. David Guyton, Professor of Ophthalmology, The Wilmer Institute. Their commitment to the development of new concepts, and their concern for the welfare of others, has been an inspiration to all of us. The development of this paper would have been impossible without their dedicated support.

CYBERNETICS: [From Gr, kybernetes, steersman, governor.] Comparative study of the control system formed by the nervous system and brain and mechanical-electrical communication systems, such as computing machines.

Strabismus surgery -- what are the alternatives

This was taken from sci.med.vision. Each post is basically unedited, except for some deletions of quoted material which would have been redundant. Some remarks of mine are added, too. I offer this as an example of the kind of runaround you get when you try to get honest answers about treatment for vision. --Alex

Subject: Advice needed on strabismus surgery

Date: Sun, 1 Oct 1995 00:02:46 GMT

Our 2 year old daughter has strabismus. Two pediatric ophthalmologists have recommended eye surgery to straighten her eyes. They have also told us that if we wait too long to have the problem corrected, her eyes may never fuse.

Does anyone have any information on how often this surgery is successful, what problems can occur, and what alternatives there are. Are eye exercises or other non-surgical techniques successful? Is the surgery likely to help her eyes fuse or is more cosmetic? Is waiting longer a waste of time? Does it reduce the chances that her eyes will ever fuse?

In general, I trust the ophthalmologists, but there are so many surgical procedures (hysterectomies, heart bypasses, etc.) that are now viewed as being performed too frequently, that I'm concerned surgery for strabismus might someday be viewed the same way.

Some more background on our daughter's case.

Our daughter did not have any obvious eye problems until March of this year. In March she developed a minor cold. Shortly after the cold, her left eye would not turn out past center. After consulting with a neurologist and an ophthalmologist and having an MRI to rule out any more serious cause, her condition was diagnosed as 6th nerve palsy. Even though the palsy effected her left eye, her right eye started wandering and often crossed in. She clearly favored her left eye. Over the course of two months, the palsy disappeared and she could turn her left eye all the way out. Nonetheless, her tendency to cross her right eye continued. The ophthalmologist said she was probably far sighted and the palsy had caused her to stop fusing. We tried patching the left eye, but she still favored the left eye and wouldn't fuse. She was given glasses, which helped but she still favored the left eye and rarely fused. Then they tried a 15 degree prism on the left lense to blur her vision in her left eye so she would use the right one. This helped quite a bit. With the prism on, she would frequently use both eyes together. When they reduced the prism to 10 degrees, hoping to slowly wean her from the prism, her eyes stop fusing.

Now it has been roughly 6 months since the problem began and there hasn't been any improvement for the last month. Her ophthalmologist feels the time

Strabismus surgery -- what are the alternatives

has come for surgery. We got a second opinion from another pediatric ophthalmologist who agreed with the first one.

We appreciate any advice anyone has.

John Anderson
Judy Coe
andercoe@seanet.com

Run immediately for a second opinion of a behavioral optometrist! We have twice to three times the success rates without surgery!!!!

Please E-mail me where you are in the country and I will give you a name of someone to get a second (sounds like a third actually) opinion.

Surgery should be the final option after you have exhausted all others!

Paul Harris O.D., F.C.O.V.D., F.A.C.B.O.
Director, Baltimore Academy for Behavioral Optometry

Paul-

Please post the citations that your success in the 2 year and younger age group is 2-3 times that of surgery. Congenital esotropia surgery has roughly an 80% success rate. Its hard for me to fathom a 160% to 240% success rate.

David Granet, MD

Bottom line here seems to depend totally on the definition of "success" that you use! I would highly doubt your 80% success rate unless you are using a definition of within about 10-15 degrees of straight. It cannot be a functional definition. The 80% you state is the highest I have ever seen in the ophthalmological literature for cosmesis only, not for function!

We in optometry deal much more with assessing functional cures and do not consider a cosmetic cure only (meaning looks straight but does not have binocularity) a success. Help me here understand your criteria.

For the most part what we have seen from your literature is in the 30-35% functional cure rates and 60-65% cosmesis following one surgery.

Granted, your techniques are better now than when these studies were

Strabismus surgery -- what are the alternatives

done but I don't see how the functional cure rate has gotten up in the 80% range at all!

The articles that I could site off the top of my head are written by Ludlum and Flax and Etting and appear in the Journal of the American Optometric Association or the American Academy of Optometry. I'll look em up while off line and put up another message later with the articles.

Paul:

>> Run immediately for a second opinion of a behavioral optometrist! We
>> have twice to three times the success rates without surgery!!!!

David Granet:

>Please post the citations that your success in the 2 year and younger age
>group is 2-3 times that of surgery. Congenital esotropia surgery has
>roughly an 80% success rate. Its hard for me to fathom a 160% to 240%
>success rate.

David, the original poster was concerned with a case of ACQUIRED, not congenital esotropia. Nor was Paul talking about congenital esotropia. Why do you bring up the success rate for congenital esotropia surgery?

John M. Anderson :

>Our daughter did not have any obvious eye problems until March of this
>year. In March she developed a minor cold. Shortly after the cold, her
>left eye would not turn out past center.

What is the surgical success rate for this kind of esotropia, David?
Please post citations.

--Alex

>
> David, the original poster was concerned with a case of ACQUIRED, not
> congenital esotropia. Nor was Paul talking about congenital esotropia.

Alex you have always wanted to see discussions amongst eye care specialists on-line yet you insist on jumping in to the discussion to speak for Paul Harris. He strikes me as being able to reply for himself.

I guess its just anothe "Look at me, look at me now !" call from you.

Strabismus surgery -- what are the alternatives

David Granet, MD

> We in optometry deal much more with assessing functional cures and do
> not consider a cosmetic cure only (meaning looks straight but does not
> have binocularity) a success. Help me here understand your criteria.

What do you mean by functional ? Are you using a specific test of
binocularity ? Grade of fusion, degree of stereo ? I am not aware of any
level of binocularity in congenital esotropes using non-surgical methods.

^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^

(I guess one could use 45 prism diopter glasses on a 6 month old but I've
never seen it)

David Granet, MD

[Emphasis on congenital esotropes mine --A.E]

We tend to use Flom's criteria. Are you familiar with them???

Paul Harris, O.D., F.C.O.V.D., F.A.C.B.O.
Director, Baltimore Academy for Behavioral Optometry

David:
>Alex you have always wanted to see discussions amongst eye care
>specialists on-line yet you insist on jumping in to the discussion to
>speak for Paul Harris. He strikes me as being able to reply for himself.

I am the Alex. I speak for myself. I caught you making some very sloppy
reasoning, and will not let it slide. Shouldn't I expect high-quality
reasoning from you?

Now then.

Paul was telling John Anderson to take his son[*] to a behavioral
optometrist, because, Paul claims, behavioral optometry's methods are 2-3
times more successful than surgery at treating esotropia. You then said
that the success rate for surgery on CONGENITAL esotropia is 80%, as if
that was a contradiction to Paul's statement about the success rate
for esotropia treatment IN GENERAL. You then proceeded to ridicule Dr.
Harris, asking for the studies showing a 240% congenital strabismus

Strabismus surgery -- what are the alternatives

success rate.

But John's son's strabismus was ACQUIRED...

John M. Anderson :

>Our daughter did not have any obvious eye problems until March of this
>year. In March she developed a minor cold. Shortly after the cold, her
>left eye would not turn out past center.

For the second time, David, what is the surgical success rate for this
kind of esotropia? And don't forget to give us the references to the
double-blind-cross-eyed studies that support the statistic.

--Alex

[*] Acutally it was his daughter! (See quote!) I admit I screwed up on
this post! Funny David didn't catch me on this one!

> I am the Alex. I speak for myself. I caught you making some very sloppy
> reasoning, and will not let it slide.

"I am the Alex". Is this using the third person ? Are you that full of
yourself to address yourself in this way ? This is like saying, "I am the
King". Earn something, anything, and then take pride.

As to your expertise, in this field, everyone on-line here already knows
it is non-existent.

David

As an expert in semantics, I felt it is my duty to point out your
misleading conflation of "acquired" and "congenital".

John Anderson wanted to know if surgery was the best thing for his child,
who had acquired esotropia at the age of 2 after having a cold.

Paul said behavioral optometrists' therapy is 2-3 times more successful than
surgery for esotropia.

You said, no, that can't be true because surgery for acquired esotropia
is 80%.

As I have pointed out several times, you simply cannot contradict a

Strabismus surgery -- what are the alternatives

statement about the relative success rate of esotropia treatments with a statistic on the success rate for ONE TYPE of esotropia. All the more so, when it is precisely NOT THAT TYPE of estotropia that is in question. If a man wants to know how much vitamin C apples have, do you quote statistics on oranges? Of course not. If a man wants to know if surgery will help his child with acquired esotropia, do you reassure him with a statistic on congenital esotropia?

Well, I guess the laws of logic don't apply when doctors are trying to talk people into surgery.

As a citizen with an interest in eyecare issues, I would like to know the statistic you are taking such pains to avoid discussing.

What is the success rate for surgery on acquired esotropia?

--Alex

I am the Alex. I speak for myself. I don't need a thneed.
(Apologies to Dr. Seuss)

> What is the success rate for surgery on acquired esotropia?

Alex, you have given advice to many different folks on-line previously. I am shocked that you ask the above question without recognizing its inherent catch-22.

While I am more than willing to discuss eye care issues on-line I have not and (as you know) will not tutor you on-line. Your chotzpah in giving advice in a field you continually demonstrate that you are exceedingly unfamiliar with is mind boggling.

I advise once again that your *extended and tedious* education take place at your university.

Best of luck in your education. Stop back in after it has actually begun.

Organizations Involved in Vision Improvement

The following organizations all provide products and services for the purpose of improving naked-eye vision. They are not affiliated with **I SEE**, nor is their listing here intended as an endorsement of the services and products provided.

Behavioral Optometrists

These organizations can refer you to a licensed Doctor of Optometry who prescribes behavioral therapy for the eyes. As optometrists, they are licensed to prescribe lenses as well. They vary considerably in philosophy. Some are doctors who use exercises to treat cross eye, but still only prescribe glasses for nearsightedness. Others do contact-lens therapy (Ortho-K, PCM) and market it as a "natural" alternative to glasses. Very few of them are actively involved in the cause of better eyesight without glasses, but most of them are sympathetic, and will be more likely than other eye doctors to be helpful when you come saying you want specially underprescribed "training glasses".

Vision Improvement Self-Help Books

Bates Method

Classic Bates Method

These books present methods that are entirely within the framework of Bates's original theory of refractive error, accommodation, and mental strain as the primary cause of eye problems. Some, however, add advice on nutrition and physical fitness that Bates never concerned himself with in his writings.

- Bates, William Horatio. *The Cure of Imperfect Sight by Treatment Without Glasses*. (On cover: "Perfect Sight Without Glasses".) New York: Central Fixation Publ., 1920. Posthumously abridged, revised, and republished as "*The Bates Method for Better Eyesight Without Glasses*". New York: Henry Holt, 1943.
- Benjamin, Harry. *Better sight without glasses*. 1929 (1st ed). 6th ed. "...or Contact Lenses". Wellingborough: Thorsons, 1992.
- Corbett, Margaret Darst. *A quick guide to better vision; how to have good eyesight without glasses*, 1957.
- Corbett, Margaret Darst. *Help yourself to better sight*. New York, Prentice-Hall, 1949.
- Hackett, Clara A. *Relax and see: A daily guide to better vision*. New York: Harper, 1955.
- McFadden, Bernarr. *Strengthening the Eyes: A System of Scientific Eye Training*. New York, McFadden Publ, 1925.
- MacFadyen, Ralph J. *See Without Glasses*. New York: Fawcett (Premier), 1958.
- Peppard, Harold M. *Sight Without Glasses*. New York: Garden City Books, 1940.
- Price, C. S. (Cecil Stanley). *The improvement of sight by natural methods: a complete treatise upon the newer methods of treating all conditions of imperfect sight by natural means, and obviating the necessity for glasses, drugs, or operations*. 3d ed., reprinted. Cleveland: Sherwood Press, 1946. (1st ed. London, 1934).

"Second Generation" Bates

The authors of the following books never knew Bates personally, but many of them knew his students (e.g. Margaret Darst Corbett). They have all worked as vision improvement consultants. They present various philosophies of vision improvement, using Bates's ideas as a starting point, but often incorporating ideas from the tradition of behavioral optometry.

- Chaney, Earlyne. The eyes have it: a self-help manual for better vision. New York: Instant Improvement, 1991.
- Goodrich, Janet. Natural vision improvement. Berkeley, Calif. Celestial Arts, 1986.
- Hoopes, Ann. Eye power: improved self-awareness, vitality, and mental efficiency through visual training. New York: Knopf, 1979.
- Hughes, Barbara. 12 weeks to better vision: a remarkable technique to restore your eyesight. New York : Pinnacle Books, 1981.
- Leviton, Richard. Seven Steps to Better Vision. Natural Health Books, 1992.
- Mansfield, Peter. The Bates Method. Revised ed. London: Optima, 1995.
- Quackenbush, Thomas R. Relearning to See. Berkeley, CA: North Atlantic Books, 1997.
- Scholl, Lisette. Visionetics: The Holistic Way to Better Eyesight. Garden City, N.Y.: Doubleday, 1978.
- Scholl, Lisette. HypnoVision: The New Natural Way to Vision Improvement: New York: Henry Holt, 1990.
- Selby, John, The Visual Handbook, Longmead, Shaftesbury, Dorsett, UK, Element Books Ltd, 1987.

Personal Approach

The following books are written by people who discovered the Bates method, improved their vision, did a little research, and wrote a book which draws from their personal experience as well as their research.

- Huxley, Aldous. The Art of Seeing. New York: Harper, 1942. (Original edition has 273 p; later editions from various publishers have 145-158 p.)
- Rosanes-Berret, Marilyn B. Do You Really Need Eyeglasses? New York: Station Hill Press. 1990.
- Windolph, Michael. Easy eye exercises for better vision : self-helps to sight improvement. Hicksville, N.Y. : Exposition Press, 1974.

Engineering Approach to Myopia Prevention

The following books are written by engineers who make the case, using scientific evidence and engineering concepts, that myopia is caused by too much focusing at the near point. "Plus lenses" as a way to prevent myopia, and to treat it in its early stages, are discussed. These books are addressed to technically-minded readers who would like to maintain or regain their own or their children's good distance vision.

- Brown, Otis S. [How to Avoid Nearsightedness: A Scientific Study of the Eye's Behavior](#). C & O Research: 1999.
- Rehm, Donald S. The Myopia Myth: The Truth About Nearsightedness and How to Prevent It. Ligonier, PA: [International Myopia Prevention Assn.](#), 1981.

"Enlightened" Optometrists

Robert-Michael Kaplan and Jacob Liberman hold doctorate degrees in optometry, and both used to have private practice in optometry. They now work outside the established institutions of optometry; they no longer prescribe lenses. Instead, they work as consultants to optometrists and other health care providers. Their books combine ideas from the Bates method, behavioral optometry, as well as insights they have gained as optometrists.

- Kaplan, Robert-Michael. Seeing without Glasses (1987 edition titled Seeing beyond 20/20). Hillsboro, OR: Beyond Words Pub., 1994.
- Kaplan, Robert-Michael. The Power Behind Your Eyes: Improving Your Eyesight with Integrated Vision Therapy. Rochester, Vt. Healing Arts Press, 1995.
- Liberman, Jacob. Take Off Your Glasses and See: How to Heal Your Eyesight and Expand Your Insight. London: Thorsons, 1995.

Behavioral Optometry

Behavioral optometry is usually considered to be a tradition completely unrelated to Bates's school of eye education. Where the principle behind the Bates method is to enable the eye to see well without glasses or other devices in a mind-over-matter sort of way, behavioral optometry relies on "therapeutic" and "stress-reducing" lenses, patches, and mechanistic games to achieve a goal of efficient vision. Naturally, "freedom from glasses" could never be promoted by any group of optometrists who wish to remain in good standing with their peers, but the promise is there, if muted.
